1. Subbasin Assessment – Watershed Characterization

The federal Clean Water Act (CWA) requires that states and tribes restore and maintain the chemical, physical, and biological integrity of the nation's waters (33 USC § 1251.101). States and tribes, pursuant to section 303 of the CWA are to adopt water quality standards necessary to protect fish, shellfish, and wildlife while providing for recreation in and on the waters whenever possible. Section 303(d) of the CWA establishes requirements for states and tribes to identify and prioritize water bodies that are water quality limited (i.e., water bodies that do not meet water quality standards). States and tribes must periodically publish a priority list of impaired waters, currently every two years. For waters identified on this list, states and tribes must develop a total maximum daily load (TMDL) for the pollutants, set at a level to achieve water quality standards. This document addresses the water bodies in the St. Maries River Subbasin that have been placed on what is known as the "303(d) list."

The overall purpose of this subbasin assessment and TMDL is to characterize and document pollutant loads within the St. Maries River Subbasin. The first portion of this document, the subbasin assessment, is partitioned into four major sections: watershed characterization, water quality concerns and status, pollutant source inventory, and a summary of past and present pollution control efforts (Chapters 1 – 4). This information was used to develop a TMDL for each pollutant of concern for the St. Maries River Subbasin (Chapter 5).

1.1 Introduction

In 1972, Congress passed public law 92-500, the Federal Water Pollution Control Act, more commonly called the Clean Water Act. The goal of this act was to "restore and maintain the chemical, physical, and biological integrity of the Nation's waters" (Water Pollution Control Federation 1987). The act and the programs it has generated have changed over the years as experience and perceptions of water quality have changed. The CWA has been amended 15 times, most significantly in 1977, 1981, and 1987. One of the goals of the 1977 amendment was protecting and managing waters to insure "swimmable and fishable" conditions. This goal, along with a 1972 goal to restore and maintain chemical, physical, and biological integrity, relates water quality with more than just chemistry.

Background

The federal government, through the U.S. Environmental Protection Agency (EPA), assumed the dominant role in defining and directing water pollution control programs across the country. The Idaho Department of Environmental Quality (DEQ) implements the CWA in Idaho, while the EPA oversees Idaho and certifies the fulfillment of CWA requirements and responsibilities.

Section 303 of the CWA requires DEQ to adopt, with EPA approval, water quality standards and to review those standards every three years. Additionally, DEQ must monitor waters to identify those not meeting water quality standards. For those waters not meeting standards, DEQ must establish TMDLs for each pollutant impairing the waters. Further, the agency must set appropriate controls to restore water quality and allow the water bodies to meet their designated uses. These requirements result in a list of impaired waters called the "303(d) list." This list describes water bodies not meeting water quality standards. Waters identified on this list require further analysis. A subbasin assessment and TMDL provide a summary of the water quality status and allowable TMDL for water bodies on the 303(d) list. *St. Maries River Subbasin Assessment and Total Maximum Daily Loads* provides this summary for the waters currently listed in the St. Maries River Subbasin.

The subbasin assessment section of this report (Chapters 1 – 4) includes an evaluation and summary of the current water quality status, pollutant sources, and control actions in the St. Maries River Subbasin to date. While this assessment is not a requirement of the TMDL, DEQ performs the assessment to ensure impairment listings are up to date and accurate. The TMDL is a plan to improve water quality by limiting pollutant loads. Specifically, a TMDL is an estimation of the maximum pollutant amount that can be present in a waterbody and still allow that waterbody to meet water quality standards (40 CFR, Part 130). Consequently, a TMDL is waterbody- and pollutant-specific. The TMDL also includes individual pollutant allocations among various sources discharging the pollutant. The EPA considers certain unnatural conditions, such as flow alteration, a lack of flow, or habitat alteration, that are not the result of the discharge of a specific pollutants as "pollution." A TMDL is not required for water bodies impaired by pollution, but not specific pollutants. In common usage, a TMDL also refers to the written document that contains the statement of loads and supporting analyses, often incorporating TMDLs for several water bodies and/or pollutants within a given watershed.

Idaho's Role

Idaho adopts water quality standards to protect public health and welfare, enhance the quality of water, and protect biological integrity. A water quality standard defines the goals of a waterbody by designating the use or uses for the water, setting criteria necessary to protect those uses, and preventing degradation of water quality through antidegradation provisions.

The state may assign or designate beneficial uses for particular Idaho water bodies to support. These beneficial uses are identified in the Idaho water quality standards and include:

-- Aquatic life support – cold water, seasonal cold water, warm water, salmonid spawning

-- Contact recreation – primary (swimming), secondary (boating)

-- Water supply – domestic, agricultural, industrial

-- Wildlife habitats, aesthetics

The Idaho legislature designates uses for water bodies. Industrial water supply, wildlife habitat, and aesthetics are designated beneficial uses for all water bodies in the state. If a waterbody is unclassified, then cold water and primary contact recreation are used as additional default designated uses when water bodies are assessed.

A subbasin assessment entails analyzing and integrating multiple types of waterbody data, such as biological, physical/chemical, and landscape data to address several objectives:

- Determine the degree of designated beneficial use support of the waterbody (i.e., attaining or not attaining water quality standards).

- Determine the degree of achievement of biological integrity.

- Compile descriptive information about the waterbody, particularly the identity and location of pollutant sources.

- When water bodies are not attaining water quality standards, determine the causes and extent of the impairment.

1.2 Physical and Biological Characteristics

The St. Maries River and its major tributaries (Middle Fork of the St. Maries River; West Fork of the St. Maries River and Emerald, Carpenter, Crystal, Renfro, Tyson, Santa, Charlie, John, Alder, and Thorn Creeks) drain the entire St. Maries Subbasin into the St. Joe River (Figure 1).

Climate

Northern Idaho is located in the Northern Rocky Mountain physiographic region to the west of the Bitterroot Range. The Clearwater Mountains, which the St. Maries River drains, are a part of the Bitterroot Range. The local climate is influenced by both Pacific maritime air masses from the west as well as continental air masses from Canada to the north and the Great Basin to the South. The annual weather cycle generally consists of cool to warm summers with cold and wet winters. The relative warmth of winters depends on the dominance of the warmer, wetter Pacific or cooler dryer continental air masses. The relative warmth of summers depends on the dominance of the warmer, drier Great Basin or cooler, wetter Pacific air masses. Precipitation is greatest during the winter months.

In the city of St. Maries, for a period of record from 1897 to 2001, the average annual maximum temperature was 59.6 ^{o} F and the average annual minimum temperature was 35.5 ^{o}F (Inside Idaho 2002). For the same time period, the month with the lowest average maximum (49.3 ^{o}F) and lowest average minimum (22.2 ^{o} F) temperature was January. July had the highest average annual minimum temperature (34.8^{o}F) and the highest average annual maximum temperature (84.8 ^{o}F). In the town of Clarkia, for a period of record from 1948 to 1975, the annual minimum temperature was 30.1 ^{o}F and the average annual maximum temperature was 54.8 ^{o} F (Inside Idaho 2002). For the same time period, the month with the lowest average minimum (21.1 ^{o}F) and the lowest average maximum (41.7 ^{o}F) temperature was January. July had the highest average annual minimum temperature (31.1 ^{o}F) and the highest average annual maximum temperature (83.3 ^{o}F).

Although intervening mountain ranges progressively dry the Pacific maritime air masses, these air masses deposit appreciable moisture as rain and snow on the St. Maries watershed. Maritime air masses originating in the mid-Pacific are relatively warm, often yielding their precipitation as rain. Relief of the watershed is generally between 2,150 and 4,500 feet. Forty-one percent of the watershed's land mass consists of slopes in the rain-on-snow elevation range of 3,300 to 4,500 feet. Below 3,300 feet the snow pack is transitory, while above 4,500 feet the snow pack is sufficiently cool that warming by a maritime front is insufficient to cause a significant thaw. Much of the watershed is below 3,300 feet elevation. In the rain-on-snow elevation range (3,300 - 4,500 feet), a heavy snow pack accumulates each winter. A warm maritime front can sufficiently warm the snow pack making it isothermal and capable of yielding large volumes of water to a runoff event.

Data from the city of St. Maries shows that the 105-year average annual precipitation from 1897 to 2001 was reported at 28.4 inches (Inside Idaho 2002). December exhibited the largest amount of precipitation at 3.93 inches and July the lowest amount of precipitation at 0.98 inches. Data from Clarkia shows that the 27-year average annual precipitation from 1948 to 1975 was reported at 37.5 inches. January exhibited the largest amount of precipitation at 7.06 inches and August the lowest amount of precipitation at 1.07 inches.

Subbasin Characteristics

The St. Maries River drains the western flank of the Clearwater Mountains, a subset of the Bitterroot Mountains. The river flows from the southeast to the northwest to enter the St. Joe River at the town of St. Maries, Idaho (Figure 1). The watershed encompasses 481 square miles (307,840 acres) above St. Maries.

-- Hydrography

The U.S. Geological Survey has continuously operated the Santa Gauging Station on the St. Maries River since October 1965. A weather station has operated at the St. Maries Ranger Station near the city of St. Maries since 1897, while a weather station operated at the Clarkia Ranger Station from 1948 to 1975. Data from these stations are included in this assessment.

-- Geology and soils

The general land form in the St. Maries River Subbasin is steep, but generally stable. Mass failures are not a typical feature of the land form development, but are specific to a few land types located primarily on granitic and lacustrine land forms. Historically, the Clearwater Mountains were glaciated, but not covered by ice sheets. In the broad floodplain of the lower St. Maries, alluvial materials worked by the river comprise the valley bottoms. Some reaches of the St. Maries River are located on lacustrine deposits of a late Eocene Lake. Lower reaches of the St. Maries River are located on lacustrine deposits of Miocene Coeur d'Alene Lake. Wetlands and a few lateral lakes occur in the lower river valley above St. Maries.

Bedrock in the subbasin is primarily composed of metasedimentary rocks of the Proterozoic Belt Supergroup. The Belt formations of St. Maries River valley are mud and sandstone of the younger Missoulian series. Columbia Plateau basalt flows are common from the city of St. Maries to Fernwood. Granitic intrusions exist in a few areas. Bedrock underlying the upper end of the valley is likely Belt rock metamorphosed by emplacement of the Idaho Batholith to the south. Commercial placer deposits of garnet that have weathered from these materials are located in Carpenter and Emerald Creeks. Gold deposits were developed in Tyson Creek (Russell 1979).

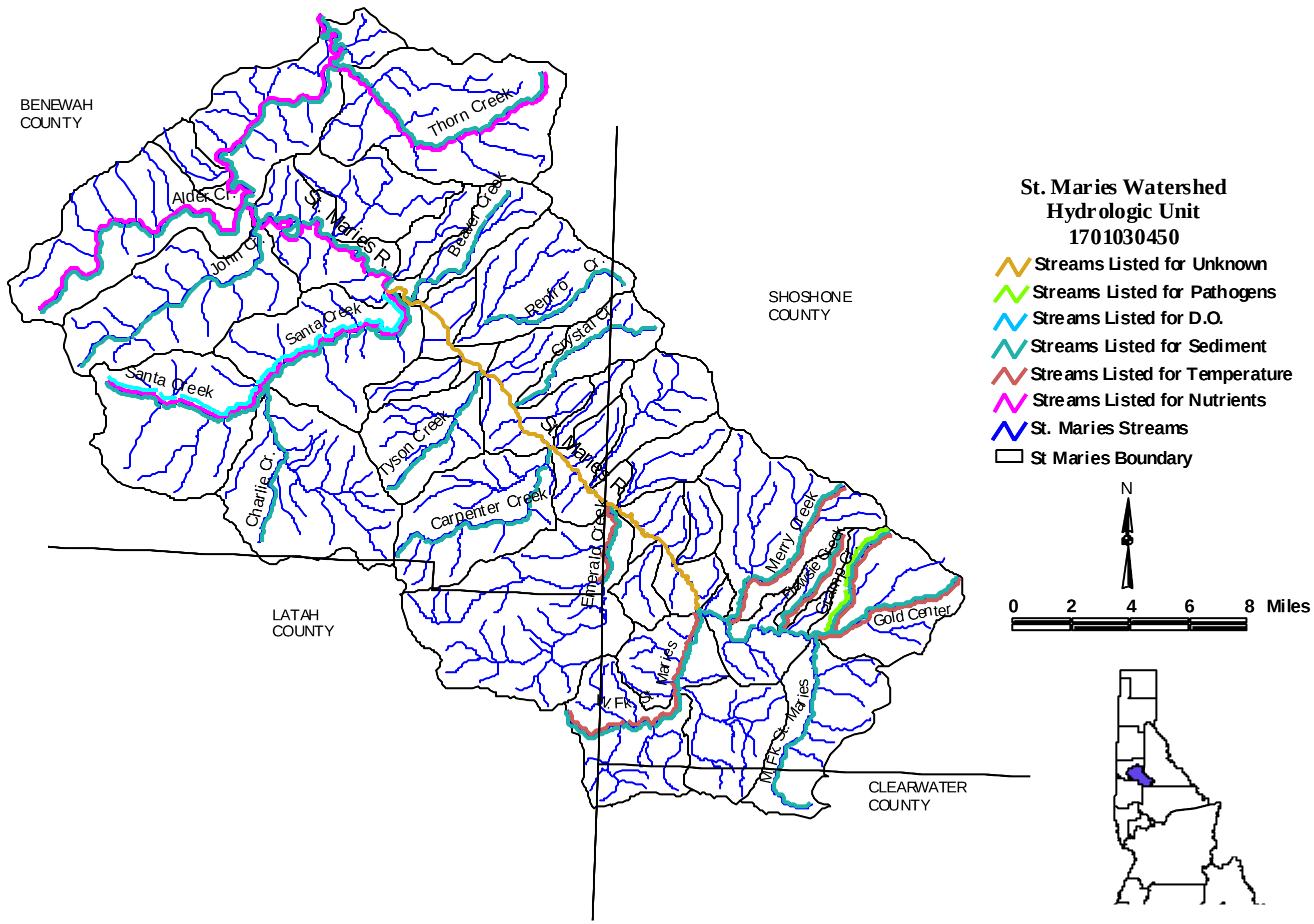

Figure 1. St. Maries Subbasin and 303(d) Listed Streams

The mountain slopes are generally underlain by silty to silt loam podsolic soils developed under cool conditions. Sandy granitic soils occur in a few areas. Palouse loess silt loam is found in the western watersheds of the subbasin. Volcanic ash deposits are variably found in the soil mantle. The soil mantle is thin to deep on slopes with A and B horizons of 3 to 4 inches. Soil mantle generally decreases with altitude. Soils in the bottomlands may be silty to sandy podsols developed under upland forest. Near streams and in some pockets, black mucky soils exist where western red cedar (*Thuja plicata*) stands are the dominant vegetation.

-- Topography

The western flank of the Clearwater Mountain range has low rounded mountains with relatively broad intermountain valleys. Valleys range down to 2,200 feet while most mountains reach over 4,000 feet. The slopes are moderately steep on the western flank of the valley and steeper on the east. The aspect of the St. Maries River valley is generally northwest facing. Tributary valleys have a predominance of north and south facing aspects.

-- Vegetation

The mountain slopes are mantled with a mixed coniferous forest of true fir (*Abies spp.*), Douglas fir (*Pseudotsuga menziesii*), larch (*Larix spp.*), and pine (*Pinus spp.*). Forest harvest has occurred at significant levels in all watersheds of the basin. Rivers and streams are flanked by riparian stands dominated by cottonwood (*Populus spp.*) at lower elevations and alder (*Alnus spp.*) in the higher valleys. The lower St. Maries valley floor is comprised of lands on lacustrine deposits. These lands have been converted to pasture to varying degrees. Lateral wetlands are found in the lower river floodplain. Aquatic vegetation species such as rush (*Juncus spp.*), sedges (*Carex spp.*), and cattail (*Typha latifolia*) are common in these wetlands. Some floodplain fields have been converted to the cultivation of wild rice (*Zizania spp.*).

-- Fisheries and aquatic fauna

The native salmonids of the streams of the subbasin are cutthroat trout (*Oncorhynchus clarki)* and mountain whitefish (*Prosopium williamsoni*). Sculpin (C*ottus spp.*) and shiners (*Notropis spp.*) are non-salmonid natives. The tailed frog (*Ascaphus truei*), Idaho giant salamander (*Dicamptodon aterrimus*), and painted turtle (*Chrysemys picta*) complete the vertebrate species living in the streams. The fish populations of the river and some of its tributaries have been altered by the introduction of rainbow trout (*Oncorhynchus mykiss*) and brook trout (*Salvelinus fontinalis*). Non-native pike (*Esox lucius*) and small mouth bass (*Micropterus dolomieu*) are present in the lower St. Maries River. The wide shallow nature of the St. Maries River channel results in high summer water temperatures. This situation depresses trout populations and favors warm water species. Macroinvertebrates, including the crayfish (*Pacifastacus spp.*), are common in the St. Maries River.

Idaho considers cutthroat trout a sensitive species. Bull trout (*Salvelinus confluentus*), a federally threatened species, have been reported on occasion in the basin. Idaho does not consider the St.

Maries River watershed as a key bull trout watershed (Batt 1996). No other sensitive, threatened or endangered species are known to exist in the subbasin.

Subwatershed Characteristics

The subwatershed characteristics are summarized in Table 1.

Table 1. Watershed characteristics of the fifth order watersheds of the St. Maries River Subbasin.

Fifth Order Watershed	Area (acres)	Land Form	Dominant Aspect	Relief Ratio[1]	Mean Elevation (m)	Dominant Slope (%)	Hydrologic Regimes	Estimated Water Yield (acre-feet/year)	Mass Wasting Potential
Middle Fork St. Maries River	16,190	Mountainous	West	0.0617	1,275	20%-30%	Spring snowmelt; rain-on-snow	24,053	low
Gold Center Creek	10,929	Mountainous	West	0.0939	1,307	>40%	Spring snowmelt; rain-on-snow	16,095	low
Flewsie Creek	2,049	Mountainous	West	0.0706	1,084	20%-30%	Spring snowmelt; rain-on-snow	3,017	low
Merry Creek	14,275	Mountainous	West	0.0726	1,797	20%-30%	Spring snowmelt; rain-on-snow	21,022	low
Cats Spur Creek	7,847	Mountainous	West	0.0658	1,140	20%-30%	Spring snowmelt; rain-on-snow	11,556	moderate
West Fork St. Maries River	15,902	Mountainous	East	0.0564	1,200	20%-30%	Spring snowmelt; rain-on-snow	23,420	moderate
Emerald Creek	11,137	Mountainous	East	0.0395	1,084	20%-30%	Spring snowmelt; rain-on-snow	16,401	moderate
Olsen-Childs Creeks	17,734	Mountainous	South	0.0598	959	0%-10%	Spring snowmelt; rain-on-snow	26,116	low
Carpenter Creek	12,852	Mountainous	East	0.0527	1,069	20%-30%	Spring snowmelt; rain-on-snow	18,928	moderate
Crystal Creek	5,340	Mountainous	West	0.0706	1,196	30%-40%	Spring snowmelt; rain-on-snow	7,864	low
Renfro Creek	11,165	Mountainous	West	0.0619	1,102	20%-30%	Spring snowmelt	16,443	low
Tyson Creek	8,035	Mountainous	East	0.0693	1,012	20%-30%	Spring snowmelt; rain-on-snow	11,834	low
Beaver Creek	8,677	Mountainous	West	0.0580	1,023	20%-30%	Spring snowmelt; rain-on-snow	7,330	low
Charlie Creek	17,385	Mountainous	West	0.0460	1,109	30%-40%	Spring snowmelt; rain-on-snow	25,603	low
Santa Creek	29,941	Mountainous	East	0.0409	991	20%-30%	Spring snowmelt; rain-on-snow	44,094	low
John Creek	16,209	Mountainous	East	0.0344	955	30%-40%	Spring snowmelt; rain-on-snow	23,871	low
Thorn Creek	11,925	mountainous	West	0.0404	956	0%-10%	Spring snowmelt; rain-on-snow	17,562	low
Lower St. Maries Sidewalls	23,514	mountainous	East	0.0322	874	>40%	Spring snowmelt; rain-on-snow	34,628	low

[1]$R_h = H/L$, where H is the difference between the highest and lowest point in the basin and L is the horizontal distance along the longest dimension of the basin parallel to the main stream line.

Stream Characteristics

Tributaries to the St. Maries River generally have V-shaped valleys as a result of the deeply dissected nature of the topography in their upper reaches. Near the valley bottoms the tributaries are of a lower gradient with meandering courses. The tributary valleys accommodate primarily Rosgen A and high gradient B channels in the upper watersheds and Rosgen C channels near their mouths. The tributaries are generally bound by boulder-bedrock substrate. The bedrock that underlies much of the subbasin weathers to soils fairly rich in fine fragments (70-80%) and rather poor in coarse materials (20-30%). There are exceptions where Belt Supergroup terrain predominates and coarse fragments constitute 50% of the soils. In the western subwatersheds where Palouse soils predominate, nearly all are fine grained. Silts dominate the valley bottom as the tributaries approach the river. In steep tributary gradients, boulders and cobble comprise the majority of the stream sediment particles. Width to depth ratios are low in these streams. The low gradient C channels of the tributaries have fine stream sediment particles and a higher width to depth ratio. Floodplains are narrow in most upper tributary channels. Broader floodplains are found in the lower reaches. Correspondingly, riparian communities are narrow in the narrow valleys and broader where valleys and floodplains widen.

The two forks of the St. Maries River above the town of Clarkia are primarily meandering Rosgen C channels except in their highest reaches. At Clarkia, the Middle and West Forks join to form the main stem of the St. Maries River. There the river traverses the bed of an Eocene lake. Consequently, the gradient generally accommodates a low (0.2-0.3%) Rosgen C channel, whose course meanders through a broad valley above the town of Mashburn. Miocene Columbia basalt flows constrict the river against Lindstrom Peak below Mashburn for approximately 10 miles. Although the river flows through this reach in a deep canyon, it maintains a meandering pattern that likely predates the basalt flows. In the canyon, the channel varies from a low gradient Rosgen B to a C channel (Rosgen 1985). The river valley widens progressively as the river swings northeast towards the town of St. Maries and its confluence with the St. Joe River. Here, the channel is a very low gradient (> 0.1%) Rosgen F channel that meanders through a broad floodplain with lateral wetlands. Sands dominate the river sediment throughout its upper course with the occasional cobble riffle, while silts are the dominant particle size of the lower river reach.

1.3 Cultural Characteristics

The St. Maries River Subbasin has timber, rangeland, and gemstone resources. These natural resources have been developed since the early 1900s. Timber harvest, placer garnet mining, and grazing of streamside pastures have affected nearly all of the tributaries and floodplains of the St. Maries Subbasin.

Additionally, the Coeur d'Alene Tribe's aboriginal territory takes in all of the St. Joe and St. Maries watersheds. Today, the Coeur d'Alene Tribal people return to this land just like their ancestors did to hunt, gather and practice cultural traditions. The Coeur d'Alene's used these waters for subsistence living in the past and will continue to do so in the future.

Land Use

Land use in the St. Maries Subbasin is divided between the uplands and the valley bottoms. The uplands are forested, while the valley bottoms are used for agriculture and grazing.

Forestlands are in multiple ownership (Figures 2a-h) with varying management direction. National Forest Lands are managed for multiple resource outputs (timber, water, and recreation). State Forest Lands are managed for timber values to support the state School Trust Fund. Commercial forestlands are managed primarily for timber production. Privately owned forestlands are managed for several resource outputs.

Farm and grazing lands are located in the lower reaches of the tributaries and in the bottomlands along the West Fork, Middle Fork and main stem of the St. Maries River. Land used for grazing is more common than cultivated farm fields.

Commercial placer mining of garnet-enriched sands occurs on the floodplains of Emerald and Carpenter Creeks. The mining activities have disrupted the channels and floodplains of these streams. In recent years, reclamation of mined lands and stream channel rehabilitation have occurred. Gold mining with hydraulic and placer methods occurred in Tyson Creek during the 1900s (Russell 1979).

Land Ownership, Cultural Features, and Population

Management of the 307,485-acre watershed is divided among land owned by private owners consisting primarily of timber companies (180,864 acres; 59%), the United States Forest Service (USFS) (66,467 acres; 22%), the State (54,939 acres; 18%), the Bureau of Land Management (BLM) (3,440 acres; 1%), and the Bureau of Indian Affairs (BIA) (1,552 acres; 0.5%). The remaining area consists of open water or riverbank (223 acres; 0.07%) (IDL GIS Database). Potlatch Corporation is the single largest commercial forest landowner, while Crown Pacific and Bennett Timber Companies have some holdings. A considerable amount of forestland is in small private tracts. Private properties, exclusive of those owned by timber companies, are situated on bottomland along the lower St. Maries River and tributaries such as Crystal, Flat, Santa, Charlie, Carpenter and Emerald Creeks. Many tributary watersheds supported large logging operations during the earlier part of the twentieth century.

Four recreation areas (three campgrounds and a recreational garnet panning area) are located in the watershed. There are three wastewater treatment facilities with National Pollutant Discharge Elimination System (NPDES) permits. These are the Santa-Fernwood, Emida, and Clarkia facilities. These permits were issued in the 1970s. The Emerald Creek Garnet Mill near Clarkia does not discharge. No dams are located in the watershed.

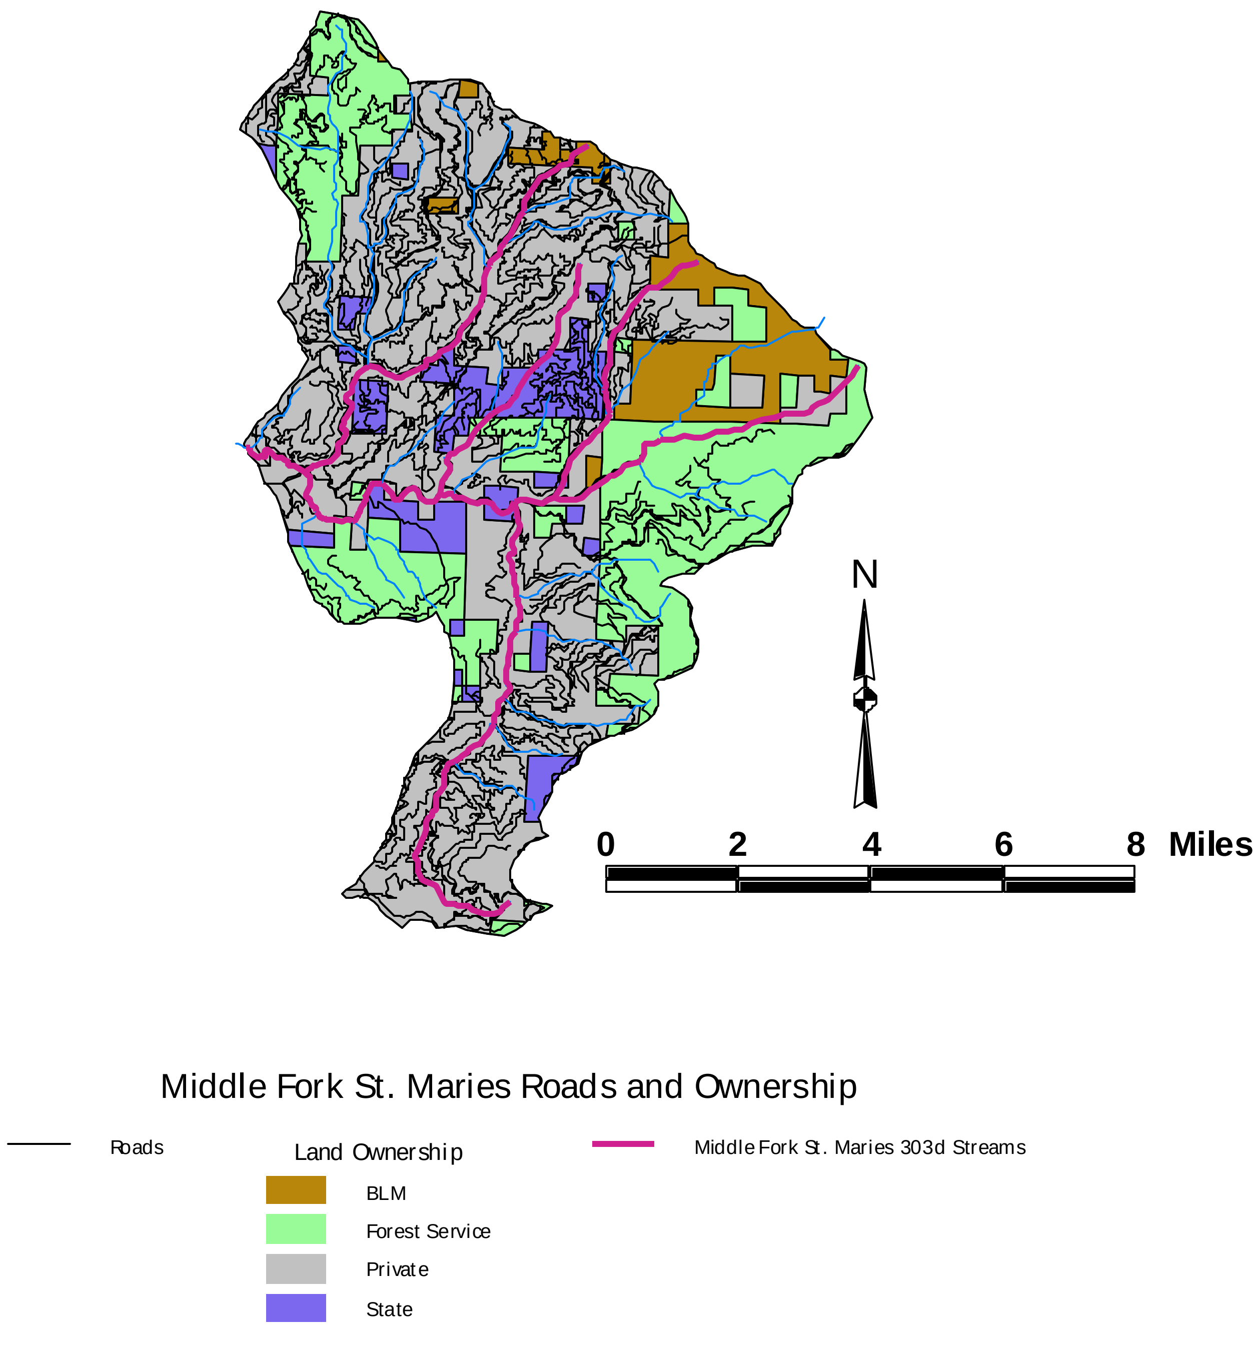

Figure 2-f. Roads and Ownership: Middle Fork of the St. Maries River

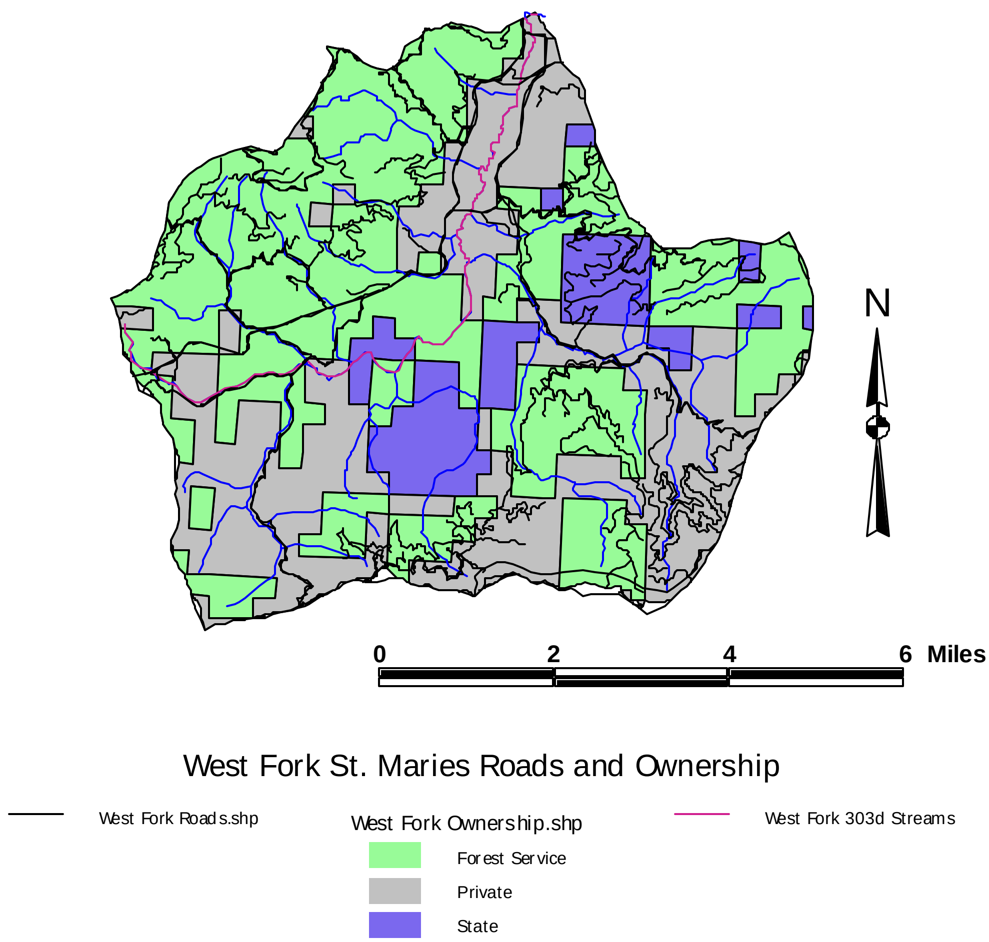

Figure 2-g. Roads and Ownership: West Fork of the St. Maries River

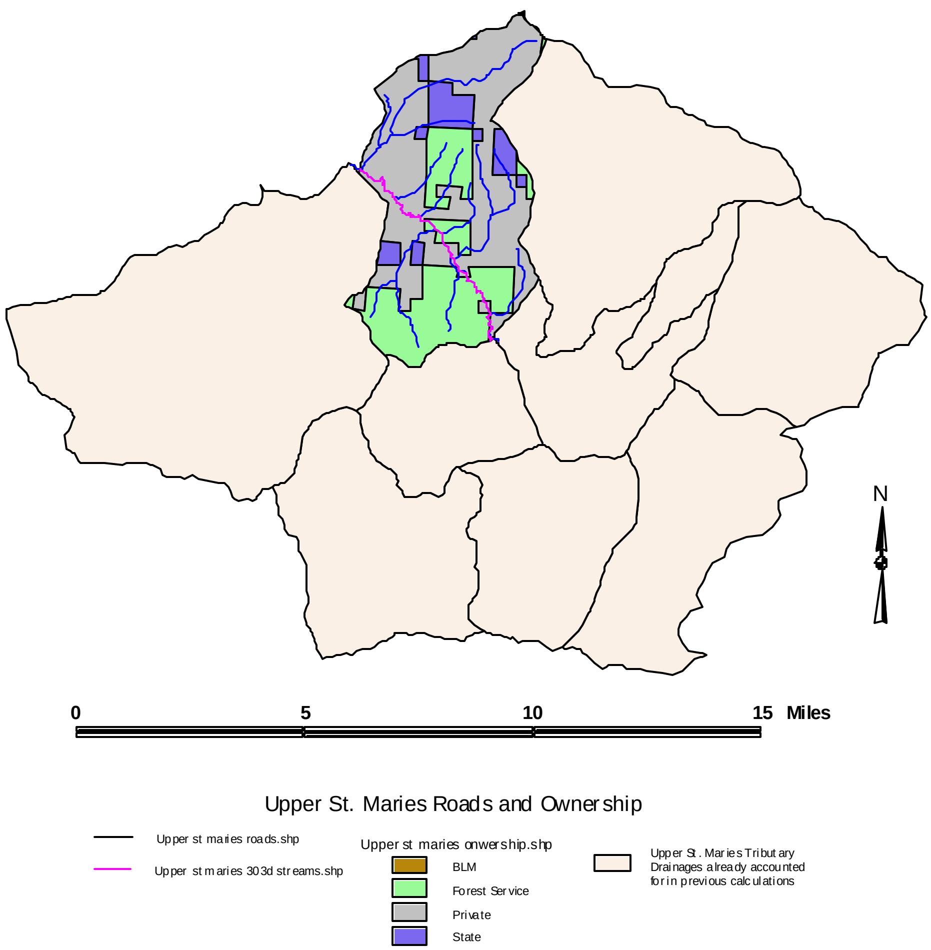

Figure 2-h. Roads and Ownership: Upper St. Maries River

Much of the St. Maries watershed is in Benewah County. The county's population is stable with approximately 9,200 residents. Roughly half of its residents live in the subbasin. St. Maries is the largest town in the subbasin and is the county seat. It has a population of 2,500. Additionally, five small towns are located in the St. Maries Subbasin: Mashburn, Fernwood, Santa, Emida, and Clarkia. None of these has a population in excess of 100. The resident and seasonal populations are sparse in the remainder of the watershed.

History and Economics

The St. Maries Subbasin was settled and developed during the early decades of the twentieth century (Russell 1979). Many watersheds within the subbasin have sustained appreciable timber harvest during the twentieth century. Logging companies initially used the waterways as the log transport system. Log flumes, some splash dams and log drives were used to move logs to mills near the city of St. Maries. Log transport by water was inefficient due to the low gradient of the river and ended by the early 1920s. However, splash dams and log drives caused some structural disruptions to the streams. Railroad logging was also practiced in some watersheds. Later, roads were built in the stream bottoms, fundamentally altering stream gradient and stability. From the 1940s to the 1970s, timber harvest depended on this extensive road network. Logging with the early jammer systems necessitated roads at approximately 100-yard intervals on the slopes. The result is a network of forgotten roads, which intercept the natural drainage system at numerous locations throughout its dendritic pattern. These mid-century harvests also relied heavily on clear-cut prescriptions.

Grazing in the St. Maries River Subbasin is restricted to the river valley and to the low gradient sections of tributary streams. Grazing impacts occur on Emerald Creek, Carpenter Creek, Santa Creek, Charlie Creek, West and Middle Forks, and the St. Maries River where cattle graze in large concentrations. Impacts typically include bank erosion caused by riparian vegetation damage.

Economically important deposits of garnet have been developed in Emerald and Carpenter Creeks. The garnet is processed for use in industrial abrasives. Garnets were mined by placer techniques in the past. In addition, stream courses were altered by dredge mining that was practiced on the floodplains. Altered stream courses are likely a source of sediment. Gold was mined by hydraulic and placer methods in Tyson Creek (Russell 1979). In recent years reclamation of stream channels and floodplains has occurred.

The Benewah Soil and Water Conservation District has been active in addressing soil and water conservation issues in the subbasin for many years. The agency has also been active in stream bank stabilization efforts. They have recently formed the core of the St. Joe Subbasin Watershed Advisory Group (WAG) along with representatives of the Coeur d'Alene Tribe, Idaho Department of Fish and Game, Idaho Department of Lands (IDL), Potlatch, Corporation, Emerald Creek Garnet, Corporation, and the USFS. The St. Joe WAG is providing input regarding the St. Joe and St. Maries Subbasin assessments and will advise DEQ on required TMDLs and implementation plans.

2. Subbasin Assessment – Water Quality Concerns and Status

The St. Maries River and nearly all of the stream segments in its watershed are listed as water quality limited under Section 303(d) of the CWA. Sediment is uniformly listed as the pollutant of concern. Nutrients, temperature, dissolved oxygen depletion, and bacteria are also listed as pollutants of concern for some segments. Fish and macroinvertebrate population surveys (DEQ Beneficial Use Reconnaissance Program [BURP]) data indicate that sediments may have contributed to the decline of trout populations in the St. Maries River and its tributaries.

2.1 Water Quality Limited Segments Occurring in the Subbasin

The St. Maries River Subbasin has 17 water quality limited 303(d) listed stream segments according to the 1998 303(d) list. These segments make up the river, its forks, and the majority of its tributary streams. Segment identification numbers, designated boundaries, and reasons for listing are shown in Table 2 and mapped in Figure 1.

Sediment, temperature, and habitat alteration are the three most prevalent reasons that segments are listed. All segments are listed for sediment with the exception of the St. Maries River between Clarkia and Mashburn, where the pollutant is unknown. Five segments are listed for temperature, while eight segments are listed for habitat alteration. While degraded habitat is evidence of impairment, the EPA does not consider a waterbody to be polluted if the pollution is not a result of the introduction or presence of a pollutant. TMDLs are not required to be established for waterbodies impaired by pollution but not pollutants.

Four segments are listed for nutrients responsible for aquatic plant growth, while one segment each are listed for bacteria and dissolved oxygen.

Table 2. 303(d) listed segments in the St. Maries Subbasin.

Waterbody Name	Segment ID Number	Assessment Unit	1998 303(d)[1] Boundaries	Pollutants	Listing Basis[2]
St. Maries River	3579	PN015_05	Mashburn (town) to St. Joe River	Habitat alteration, nutrients, sediment, and temperature	Appedix A, 305(b) report; EPA addition
St. Maries River	3580	PN015_05	Clarkia to Mashburn	Unknown, temperature	BURP Data; EPA addition to 303(d) list
West Fork of the St. Maries River	3581	PN017_02/03 /04	Headwaters to St. Maries River	Sediment and temperature	Appendix A, 305(b) report
Middle Fork of the St. Maries River	3594	PN018_02/ 03/04/05	Headwaters to St. Maries River	Habitat alteration, sediment, and temperature	Appendix A, 305(b) report; EPA addition
Thorn Creek	3582	PN026_02/03	Headwaters to St. Maries River	Nutrients and sediment	Appendix A, 305(b) report
Alder Creek	3583	PN08_02	Headwaters to St. Maries River (trans-tribal boundary)	Nutrients and sediment	Appendix A, 305(b) report
John Creek	3584	PN09_02	Unnamed tributary (7.5 km upstream) to St. Maries River	Sediment	Appendix A, 305(b) report
Santa Creek	3585	PN010_02/ 03/04	Headwaters to St. Maries River	Dissolved oxygen, habitat alteration, nutrients, sediment, and temperature	Appendix A, 305(b) report; EPA addition
Charlie Creek	3587	PN011_02/03	Headwaters to Santa Creek	Habitat alteration and sediment	Appendix A, 305(b) report
Renfro Creek	3588	PN024_02	Headwaters to Davis Creek	Sediment	Appendix A, 305(b) report
Tyson Creek	3589	PN013_02/03	North Fork Tyson Creek to St. Maries River	Habitat alteration and sediment	Appendix A, 305(b) report
Crystal Creek	3590	PN023_02	Headwaters to St. Maries River	Sediment	Appendix A, 305(b) report
Carpenter Creek	3591	PN014_02/03	Headwaters to St. Maries River	Habitat alteration and sediment	Appendix A, 305(b) report
Emerald Creek	3593	PN016_03	East Fork –West Fork Confluence to St. Maries River	Habitat alteration, sediment, and temperature	Appendix A, 305(b) report; EPA addition

[1]Refers to a list created in 1998 of water bodies in Idaho that did not fully support at least one beneficial use. This list is required under section 303 subsection “d” of the Clean Water Act.
[2]305(b) report - a report on the condition of all Idaho surface waters; EPA addition - refers to EPA additions to the1ist created in 1998 of water bodies in Idaho that did not fully support at least one beneficial use.

2.2 Applicable Water Quality Standards

Water quality standards prescribe the use of the waterbody and establish the water quality criteria that must be met to protect designated uses. Designated uses for the St. Maries Subbasin and the applicable water quality standards appear below.

Beneficial Uses

Idaho water quality standards require that surface waters of the state be protected for beneficial uses, wherever attainable (IDAPA 58.01.02.050.02). These beneficial uses are interpreted as existing uses, designated uses, and "presumed" uses as briefly described in the following paragraphs. The *Waterbody Assessment Guidance*, second edition (Grafe *et al.* 2002) gives a more detailed description of beneficial use identification for use assessment purposes.

Existing Uses

Existing uses under the CWA are "those uses actually attained in the waterbody on or after November 28, 1975, whether or not they are included in the water quality standards." The existing in stream water uses and the level of water quality necessary to protect the uses shall be maintained and protected (IDAPA 58.01.02.003.35, .050.02, and 051.01 and .053). Existing uses include uses actually occurring, whether or not the level of quality to fully support the uses exists. Practical application of this concept would be when a waterbody could support salmonid spawning, but salmonid spawning is not yet occurring.

Designated Uses

Designated uses under the CWA are "those uses specified in water quality standards for each waterbody or segment, whether or not they are being attained." Designated uses are simply uses officially recognized by the state. In Idaho these include things like aquatic life support, recreation in and on the water, domestic water supply, and agricultural use. Water quality must be sufficiently maintained to meet the most sensitive use. Designated uses may be added or removed using specific procedures provided for in state law, but the effect must not be to preclude protection of an existing higher quality use such as cold water aquatic life or salmonid spawning. Designated uses are specifically listed for waterbodies in Idaho in tables in the Idaho water quality standards (see IDAPA 58.01.02.003.22 and .100, and IDAPA 58.01.02.109-160 in addition to citations for existing uses).

The St. Maries River has designated beneficial uses (Table 3) of cold water aquatic life and primary contact recreation. The portion of the river from the confluence of the West Fork and Middle Fork of the St. Maries River to the Carpenter Creek reach of the river has the additional designated uses of domestic water supply and special resource water. Santa Creek has designated beneficial uses of cold water aquatic life, salmonid spawning and primary contact recreation (IDAPA 58.01.02.101.11). Beneficial uses have not been designated for the other tributaries of the St. Maries River.

Presumed Uses

In Idaho, most waterbodies listed in the tables of designated uses in the water quality standards do not yet have specific use designations. These undesignated uses are to be designated. In the interim, and absent information on existing uses, DEQ presumes that most waters in the state will support cold water aquatic life and either primary or secondary contact recreation (IDAPA 58.01.02.101.01). To protect these so-called "presumed uses," DEQ will apply the numeric criteria cold water and primary or secondary contact recreation criteria to undesignated waters. If in addition to these presumed uses, an additional existing use, (e.g., salmonid spawning) exists, because of the requirement to protect levels of water quality for existing uses, then the additional numeric criteria for salmonid spawning would additionally apply (e.g., intergravel dissolved oxygen, temperature). However, if for example, cold water is not found to be an existing use, a use designation to that effect is needed before some other aquatic life criteria (such as seasonal cold) can be applied in lieu of cold water criteria (IDAPA 58.01.02.101.01).

Water Quality Standards

Water quality criteria supportive of beneficial uses are stated in the Idaho Water Quality Standards and Wastewater Treatment Requirements (DEQ 2000a). The standards supporting beneficial uses are outlined in Table 5. In addition to these standards, cold water and salmonid spawning are supported by sediment and nutrient narrative standards. The narrative sediment standard states:

Sediment shall not exceed quantities specified in section 250 and 252 or, in the absence of specific sediment criteria, quantities which impair designated beneficial uses. Determinations of impairment shall be based on water quality monitoring and surveillance and the information utilized as described in Subsection 350 (IDAPA 58.01.02.200.08).

The excess nutrients standard states:

Surface waters of the state shall be free from excess nutrients that can cause visible slime growths or other aquatic growths impairing designated beneficial uses (IDAPA 58.01.02.200.06).

Table 5. Water quality standards supportive of beneficial uses (IDAPA 58.01.02.250). [1]

Pollutant	Primary Contact Recreation	Secondary Contact Recreation	Cold Water Aquatic Life	Salmonid Spawning
pH	-	-	pH between 6.5 and 9.5	pH between 6.5 and 9.5
Coliforms and dissolved gas	126 E. coli/100mL geometric mean over 30 days	126 E. coli/100mL geometric mean over 30 days	Dissolved gas not exceeding 110%	Dissolved gas not exceeding 110%
Chlorine	-	-	Total chlorine residual less than 19 ?g/L/hr or an average 11 ?g/L/4 day period	Total chlorine residual less than 19 ?g/L/hr or an average 11 ?g/L/4 day period
Toxic substances	-	-	Less than toxic substances set forth in 40 CFR 131.36(b)(1) Columns B1, B2, D2	Less than toxic substances set forth in 40 CFR 131.36(b)(1) Columns B1, B2, D2
Dissolved oxygen	-	-	Exceeding 6 mg/L D.O.	Exceeding 5 mg/L intergravel D. O.; exceeding 6 mg/L surface
Temperature	-	-	less than 22 ^{o}C (72 ^{o}F) instantaneous; 19 ^{o}C (66 ^{o}F) daily average or natural background, if greater	Less than 13 ^{o}C (55 ^{o}F) instantaneous; 9 ^{o}C (48 ^{o}F) daily average or natural background, if greater
Ammonia	-	-	Low ammonia (see formula/tables for exact concentration)	Low ammonia (see formula/tables for exact concentration)
Turbidity[2]	-	-	Less than 50 NTU instantaneous; 25 NTU over 10 days greater than background	-

[1] pH –negative logarithm of the hydrogen ion concentration; E. coli - *Escherichia coli;* ?g/L – micrograms per liter; D.O. – dissolved oxygen; mg/L – milligrams per liter; ^{o}C – degrees Celsius; ^{o}F – degrees Fahrenheit; NTU – nephelometric turbidity units.
[2] The turbidity standard is a standard applied to the mixing zones of point discharges in the standards (IDAPA 58.01.02.250.01.d). However, the standard is technically based on the ability of salmonids to sight feed. For this, it is applicable through the narrative sediment standard (IDAPA58.01.02.200.08) to impacts on salmonids (cold water aquatic life) wherever these may occur.

2.3 Summary and Analysis of Existing Water Quality Data

There are relatively few sources of existing water quality data for the St. Maries Subbasin. The USGS has operated a discharge gage on the St. Maries River near Santa since October 1965. Water quality data have been collected at this station intermittently since the late 1980s. These data include temperature, pH, dissolved oxygen, and aquatic plant growth nutrient measurements. Idaho Soil Conservation Commission (SCC) staff collected aquatic plant growth nutrients, dissolved oxygen and bacteria data at various sites on the St. Maries River, Thorn Creek and Santa Creek during water year 2000. Additional bacteria data were collected on Gramp Creek by DEQ in water year 2001. Beneficial Use Reconnaissance Program data was collected on all water quality limited streams. These data include habitat data, macroinvertebrate and fisheries data. The IDL Cumulative Watershed Effects (CWE) program collected data on sediment sources during the summers of 2000 and 2001.

Discharge Characteristics

The average annual discharge hydrograph (Figure 3) of the Santa gaging station indicates that the spring snowmelt event dominates the pattern of stream discharge (USGS 1996-2000). The mean high flow discharge for the past five years occurred in April at 1,213 cubic feet per second (cfs) and mean low flow discharge occurred in September at 64 cfs. Bank full discharge is in the range of 1,200 cfs. Rain-on-snow conditions can result in large flood events (Figure 4), as occurred during winter 1995-1996 (USGS 1997). The majority of the slopes in the St. Maries River watershed exist between 3,330 to 4,500 feet in elevation. Consequently, the watershed is prone to rain-on-snow events. Peak discharges during the third largest flood on record (February 1996) were estimated at 11,000 cfs.

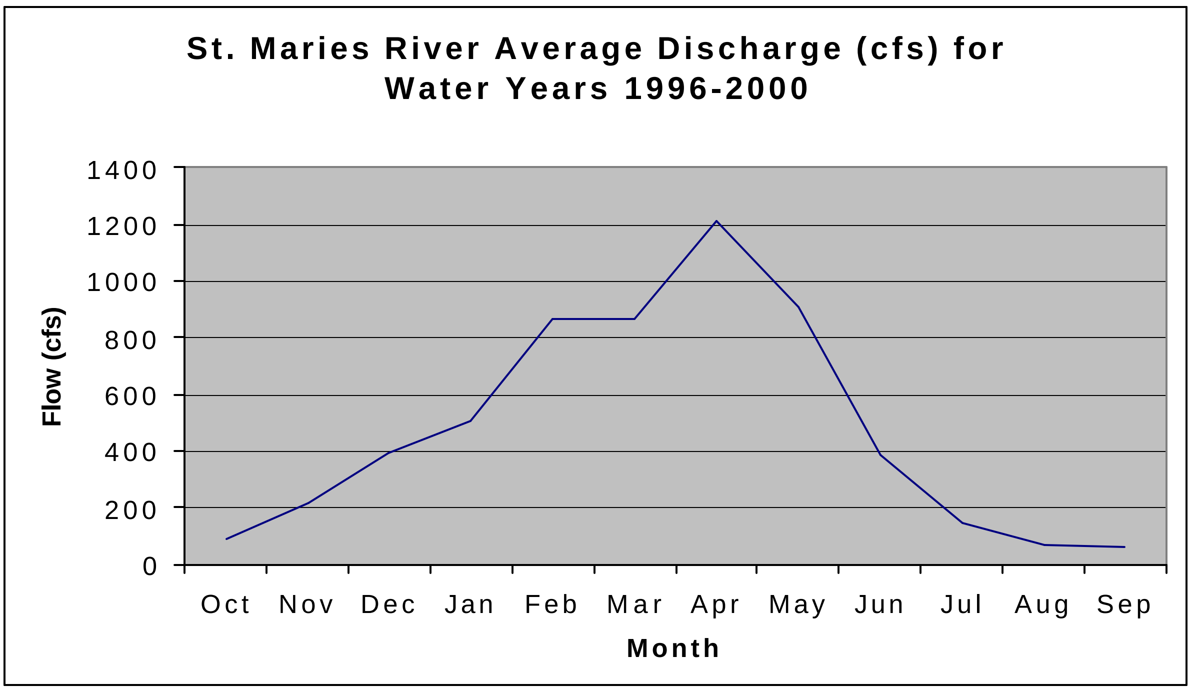

Figure 3. St. Maries River Discharge at Santa: Average Monthly Discharge for Water Years 1996-2000 (USGS 1996-2000)

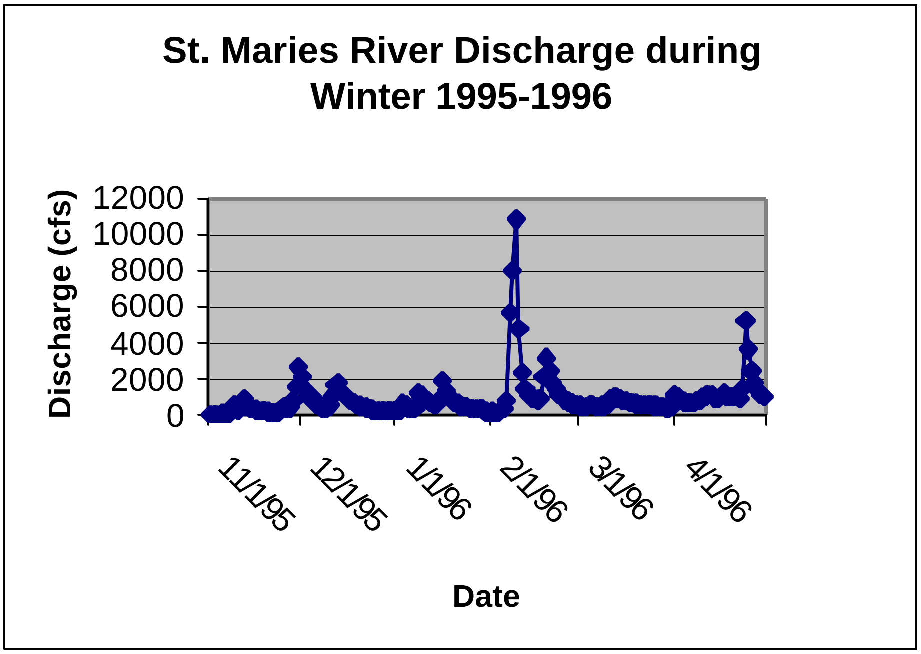

Figure 4. St. Maries River at Santa Daily Discharge During Winter 1995-1996 (USGS 1997)

Water Column Data

Water column data have been collected at the Santa gaging station by the USGS under contract with DEQ and EPA. The SCC collected aquatic plant growth nutrient and bacteria data at five locations in the subbasin. DEQ collected bacteria data at Gramp Creek to fill a data gap.

-- General data from the Santa gaging station

Selected water quality data collected by the USGS at the Santa gaging station between 1994 and 2000 are summarized in Table 7. The entire data set is provided in Appendix B.

-- Aquatic plant growth nutrients

The St. Maries River and Thorn, Alder, and Santa Creeks are listed for nutrients. Potential sources of nutrients in these watersheds include discharge from wastewater treatment facilities and livestock grazing. Three wastewater treatment facilities operate in the watershed at Clarkia, Emida, and Santa-Fernwood. The discharge monitoring records for water year 2000 from the Santa-Fernwood facility were examined. Clarkia and Emida do not assess discharge quality. Santa-Fernwood assesses total phosphorous and total Kjeldahl nitrogen in treated and receiving waters. Total phosphorous and Kjeldahl nitrogen concentrations in discharged water are low and the discharge volume is small. Stream concentration increases of phosphorous and nitrogen attributable to the discharge are negligible.

Water samples were collected on three dates during the summer of 2000 from two locations on the St. Maries River (both below the treated wastewater discharges), and at the mouths of Santa and Thorn Creeks. These samples were analyzed for total phosphorous, nitrate-nitrite and total Kjeldahl nitrogen. The analytical results are provided in Tables 8a-c. Nutrient concentrations were slightly higher at the Santa and Thorn Creek locations. Total Kjeldahl nitrogen data indicated that nitrogen was primarily in organic nitrogen forms.

The Coeur d'Alene Tribe has collected plant growth nutrient and other water column data on Alder Creek since 1997. Data is collected, on average, four to eight times a season. Nutrient data from Alder Creek is summarized in Table 9.

Gold Creek, Santa Creek, Thorn Creek, Alder Creek, and the St. Maries River were sampled for periphyton (benthic algae). High periphyton biomass may indicate eutrophic conditions. Periphyton biomass can be estimated by several methods, including determining chlorophyll *a* (chl *a*) and ash free dry mass (AFDM). The excess nutrients narrative standard requires that surface waters of the state be free from excess nutrients that can cause visible slime growths or other aquatic growths impairing designated beneficial uses. According to the EPA's *Rapid Bioassessment Protocols for Use in Wadeable Streams and Rivers* (1999), levels of algal biomass greater than 10 µg chl *a* cm^2 or greater than 5 mg AFDM cm^2 indicate nuisance levels of nutrients or organic enrichment. The periphyton samples collected from the St. Maries River and its tributaries showed levels of AFDM ranging from a low of 0.24 mg/cm^2 in Gold Creek to 1.89 mg/cm^2 in Thorn Creek. Chlorophyll *a* measured from .42 $µg/cm^2$ Gold Creek to a high of 6.68 $µg/cm^2$ in Alder Creek. All measurements were found to be well below levels causing visible slime growths or other aquatic growths impairing designated beneficial uses. It is therefore recommended that these streams be delisted for excess nutrients.

Table 6. Periphyton biomass in the St. Maries River and its tributaries.[1]

Waterbody	Sample Number	AFDM (mg/cm^2)	Chla (?/cm^2)
Gold Creek	1	0.24	0.42
Gold Creek	2	0.34	0.46
St. Maries River	1	1.83	2.68
St. Maries River	2	1.29	1.89
Santa Creek	1	1.05	2.23
Santa Creek	2	1.20	3.69
Thorn Creek	1	1.48	3.74
Thorn Creek	2	1.89	5.45
Alder Creek	1	1.11	6.68

[1]AFDM - ash free dry mass; Chla - Chlorophyll a.

Total Phosphorous	7.9	9.6	20.2	19.4	14.3

[1]Data collected by Coeur d'Alene Tribe.

?? Dissolved oxygen

Santa Creek is listed for a lack of dissolved oxygen. The dissolved oxygen concentrations of the stream were measured in late July, late August and mid September 2000 during and after a prolonged period of warm weather without precipitation. If oxygen deficiency occurs, it would be expected under these conditions. The dissolved oxygen concentrations and percent saturation measured are provided in Table 10. The values are higher than the minimum standard of 6 mg/L dissolved oxygen or 90% saturation. Based on this data, Santa Creek is not limited by low dissolved oxygen concentrations.

Table 10. Dissolved oxygen and percent saturation measured in Santa Creek near its mouth.

Date	Dissolved oxygen (mg/L)	Percent saturation
July 31, 2000	9.0	95%
August 29, 2000	10.5	103%
September 13, 2000	9.4	100%

-- Temperature

The West Fork of the St. Maries River and Emerald, Gold Center, Flewsie, and Gramp Creeks are listed as limited by temperature standard exceedences. Summer-fall temperatures were continuously monitored on these and additional tributaries of the St. Maries River. Temperature data for monitored streams are summarized in Table 11. The temperature profiles and the analyses of the data for exceedences of federal and state bull trout standards and cutthroat and bull trout spawning standards are provided in Appendix B.

Table 11. Percentage of temperature standards exceedence from federal and state bull trout standards and cutthroat and bull trout spawning standards during the period for which the standards apply.

Stream	Federal Bull Trout Exceedence: May 1 to Oct 31 (percent of days)	State Bull Trout Exceedence: May 1 to Oct 31 (percent of days)	Cutthroat Trout Spawning Exceedence: Week Post Hydrograph Peak to July 31 (percent of days)	Bull Trout Spawning Exceedence: Sept 1 to Oct 31 (percent of days)
Gramp Creek	48.4	30.4	31.0	48.4
Gold Center Creek	42.4	33.7	23.0	54.1
Flewsie Creek	57.1	48.9	54.0	32.8
MF St. Maries River	53.8	43.5	39.1	32.7
Emerald Creek – 1	58.2	51.6	66.7	41.0
Emerald Creek – 2	58.2	51.6	66.7	41.0
Emerald Creek – 3	54.9	37.5	49.4	26.2

None of the listed streams meet temperature standards. Exceedences occur between 20% and 70% of the time, depending on the standard. The BURP results employed to develop the 1998 303(d) list indicated that these streams support cold water aquatic life and salmonid spawning uses to some extent. The nearly uniform exceedence of the state and federal temperature standards during July, August, and early September suggests the standards may not be realistic. However, based on the current temperature monitoring results and temperature standards, Gramp, Gold Center, Flewsie, and Emerald Creeks, and the Middle Fork of the St. Maries River are limited by temperature. Given the results from these headwater streams, it is reasonable to assume that Santa Creek and the West Fork and main stem of the St. Maries River are also limited by temperature.

Biological and Other Data

Existing biological data include bacteria, macroinvertebrate and fisheries data. Habitat data, together with the macroinvertebrate and fisheries data, are available from the BURP database. Bacteria data were collected by the DEQ and SCC.

-- Bacteria

A single stream (Gramp Creek) is listed for bacteria. Discharge measurements of 1.3 cfs during mid-August 2000 and 1 cfs during mid-September 2001 indicate that the stream would support secondary contact recreation only. No evidence of a primary contact use was found. An assessment of *Escherichia coli* (*E. coli*) was conducted during August 2000 and September 2001. Results of the *E. coli* test indicated 13 and 17 colonies per 100 mL sample, respectively. These E. coli values are well below the criteria value of 126 E. coli/100mL for contact recreation (Table 12). Based on this data, the listing of Gramp Creek for bacteria is incorrect.

The SCC staff also collected bacteria samples in addition to nutrient samples. *E. coli* values are shown in Table 12 as *E. coli*/100 mL. These values are well below the criteria value for contact recreation of 126 *E. coli*/100 mL (Table 12). The data indicates that bacteria standards exceedence was not measured in the St. Maries River or two of its tributaries.

Table 12. *Escherichia coli* (*E. coli*/100 mL) at four locations in the St. Maries Subbasin.

Waterbody	Location	7/29/00	8/29/00	9/13/00	Mean
St. Maries River	Near Mashburn	9	62	28	33
St. Maries River	Santa Bridge	12	26	24	21
Santa Creek	Near mouth	50	24	10	28
Thorn Creek	Near mouth	10	17	42	23

-- Macroinvertebrate, fish, and habitat index data

Stream macroinvertebrate indices (SMI), stream fishery indices (SFI) and stream habitat index (SHI) scores are provided in Table 13. These data are available for several water bodies of the St. Maries River watershed. Fisheries data is the most limiting. The entire data set is provided in Appendix B. *Waterbody Assessment Guidance II* (Grafe et al. 2002) scores for the stream macroinvertebrate, fishery, and stream habitat indices based on the Northern Mountains Ecoregion are shown in the adjacent columns. These values are averaged to develop the score for the available indices. Average values of two or greater indicate support of the cold water aquatic life, while values less than two indicate nonsupport.

The data indicate that the upper reaches of the St. Maries River tributaries fully support the cold water aquatic life. Specifically, upper John, Charlie, middle Tyson, upper Carpenter, Gold Center, Gramp, Flewsie, upper Merry, upper Crystal and upper Renfro Creeks, along with the upper Middle Fork of the St. Maries River, support cold water aquatic life based on the indices and scoring system. Conversely, the following lower reaches of the tributaries and the St. Maries River do not support the cold water aquatic life: Santa, Emerald, and Thorn Creeks and the West Fork of the St. Maries River (Figure 5).

Table 13. Stream biotic indices and stream habitat index data of the St. Maries subbasin

STREAM	SMI[1]	SMI Score	SFI[2]	SFI Score	SHI	SHI[3] Score	Average SMI + SFI+ SHI	Supports Beneficial Uses

-- Additional fisheries data

Further analysis of fish populations and age class structures is shown in Table 14. John, upper Carpenter, Beaver, Tyson, upper Merry, Gramp, and Flewsie Creeks, as well as the West Fork of the St. Maries River have trout populations in the expected range of 0.1 – 0.3 trout per square meter per hour of electrofishing effort. Santa, Charlie, Renfro, Emerald, lower Merry, Gold Center, and the Middle Fork St. of the Maries River have low numbers of trout. Sculpin are present in most streams in numbers ranging from effort 0.1-0.4 fish per square meter per hour of electrofishing, with higher counts in tributary streams. Santa Creek, Charlie Creek, and the Middle and West Forks of the St. Maries river have lower than expected numbers of sculpin.

-- Sedimentation data

A visual inspection of the St. Maries River suggests bed load sediment is increased over natural background levels. The stream has a broad and shallow morphology with a very high width to depth ratio. Wetted width to depth ratios of 8.25 to 10.13 were measured at the lower and upper BURP stations, respectively, on the St. Maries River. Wetted width to depth ratios of 15.07 and 14.77 were measured at the lower Middle Fork and West Fork St. Maries River stations, respectively. A stream with a bank full flow of approximately 1,000 cfs should have a much lower width to depth ratio. Additional evidence of an increase in sediment includes a primary sediment class of fine sands on the stream bottom and point bars along the course of the river. Riffle armor stability has not been measured for streams of the St. Maries River Subbasin. However, the predominance of fine sand in the river suggests such measurement would reflect a high percentage of the bed material moving during two-year flow events.

The following sections examine quantitative information including pool volume and modeled sediment yield rates.

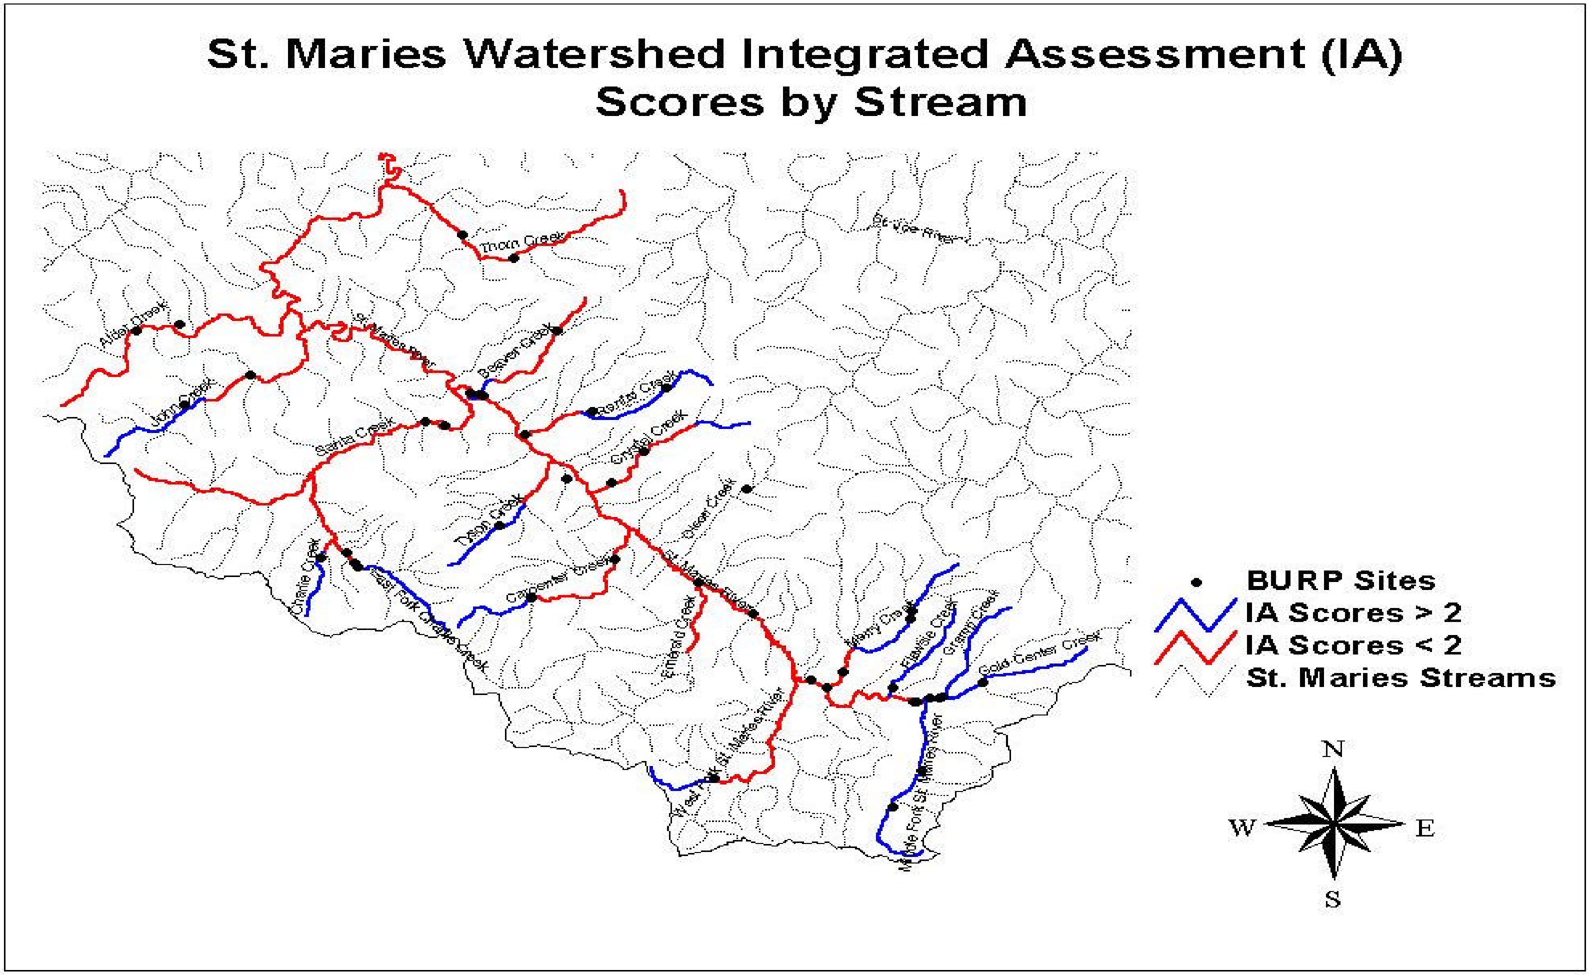

Figure 5. Stream Macroinvertebrate and Habitat Indices Scores at BURP Stations in the St. Maries Subbasin

Table 14. Fish population data in the St. Maries Subbasin.

Stream	Location	Date	Salmonids (fish/m^2/hr effort)	Sculpin (fish/m^2/hr effort)	Presence of Three Salmonid Age Classes	Presence of Tailed Frogs

Residual Pool Volume

Residual pool volume is a measure of the amount of the stream channel in pools. In theory, it is an estimate of the amount of the streambed that would hold water at zero discharge. Residual pool volume can be estimated from stream channel measurements collected by survey crews. The estimates are generally standardized on a volume per stream mile basis. Since the stream width affects the amount of pool volume possible, residual pool volume data are typically ordered based on the bank full width of the stream. Bank full width is the best measure of the typical stream discharge and ability to scour pools (DEQ 1989).

Residual pool data for the segments of the St. Maries Subbasin that are water quality limited are provided in Table 15. Streams are listed based on the bank full width of the streams. The larger the bank full width, the greater the possible residual pool volume. These streams are listed in order of increasing bank full width. Residual pool volume can be used as an indicator of the presence of fish habitat.

Table 15. Residual pool volume of St. Maries River water bodies.

Stream	Bank Full Width (ft)	Residual Pool Volume (ft^3/mi)
Crystal Creek	7.50	2,760
John Creek	8.10	11,433
Alder Creek	9.10	19,324
West Fork of the St. Maries River	9.53	7,843
Tyson Creek	10.05	6,454

Point Sources of Sediment

Three permitted discharges have total suspended solid limits (TSS). Santa-Fernwood and Clarkia are allowed discharges up to 200,000 and 150,000 gallons per day (GPD), respectively. Santa-Fernwood is restricted from discharge between November 1 and January 31. Both Santa-Fernwood and Clarkia have 30 mg/L (TSS) limits; however, they are limited to 34 and 6 pounds per day, respectively. The Emida facility does not have an NPDES permit that requires monitoring of discharge, but serves a sized population similar in size to the population served by the Clarkia facility. Based on the above limits, the fine sediment contribution of the point sources was estimated (Table 16). These sources discharge a total of 14.1 tons per year of sediment. All of this sediment is very fine material that does not cause pool filling.

Table 16. Permitted sediment discharges to the St. Maries River Subbasin.

Permitted Discharge	Average Discharge (million gallons/ day)	Total Suspended Solids Limit (mg/L)	Potential Daily Sediment Load (pounds/day)	Potential Annual Sediment Load (tons/year)
Santa-Fernwood[1]	0.2	30	34.0	6.2
Emida[2]	0.15	30	37.5	6.8
Clarkia	0.15	30	6.0	1.1
Total	0.5	-	77.5	14.1

[1]Santa-Fernwood is permitted to discharge 273 days per year maximum
[2]Emida discharges are estimated to be 30 mg/L total suspended solids and 150,000 gallons per day

Sediment Modeling

Sediment monitoring in-stream is a very time consuming and costly undertaking. In-stream sediment data collection costs estimated by URS Greiner for the Spokane River in 2001, show that in-stream sediment monitoring completed quarterly at five sites would cost $400,000 (2001). Sediment monitoring should be conducted at least annually at a site for seven years to develop a database that accounts for the variance of discharge effects on sediment yield and transport from year to year. From the URS Greiner figures, the investment required to conduct annual sediment monitoring for seven years is estimated at $140,000 per site. The time necessary and costs involved do not make sediment monitoring a viable approach for DEQ. A sediment modeling approach uses coefficients developed over long periods in paired watersheds. A sediment modeling approach is the most time and cost efficient approach to estimating sediment for the purposes of TMDLs.

Land Use Data

Sediment loading can be attributed to the entire watershed. It is not necessarily restricted to the water quality limited segments of the St. Maries River Subbasin. In the following tables, sediment load is analyzed based on all contributing watersheds in the subbasin. Sediment yield is estimated from land use data developed by the USFS, Potlatch Corporation, and IDL. Fire and road coverages developed by the USFS and BLM were used to develop data for areas that had experienced two wildfires. The coverages also provided forest road mileage and road densities. After assessment by IDL specialists, CWE scores and land failure yield estimates were developed. Road land use acreage was estimated based on road length (GIS road coverage) and known right of way width. These values are reported in Table 17.

Table 17. Land use of the St. Maries River Subbasin.

[4] CWE values extrapolated from John Creek.

Sediment Yield and Export

Sediment yields were developed separately for agriculture and forest types (Table 18). Sediment contributions from road surfaces, mass failures, road encroachment, and stream bank erosion were modeled with a separate set of algorithms. Sediment yield to the stream system was assumed to be 100%. Revised Universal Soil Loss Equation (RUSLE) Model assumptions and documentation of the sediment model are provided in Appendix C.

Table 18. Estimated sediment yield coefficients.

a) Agriculture land use

Watershed	Average RUSLE[1] Coefficient
John Creek	0.030
Santa Creek and side walls	0.055
Charlie Creek	0.060
Tyson Creek	0.090
Carpenter Creek	0.090
Emerald Creek	0.020
West Fork and side walls	0.054
Cats Spur Creek	0.020
Thorn Creek	0.030
Renfro Creek	0.060
Merry Creek	0.020
Gold Center Creek	0.020
Middle Fork and side walls	0.055
Land immediate to river	0.060

[1]Revised Universal Soil Loss Equation.

b) Forestland and road uses for the St. Maries River Subbasin

Land Use Type Sediment Export Coefficient	Belt Supergroup Precambrian Meta Sediments	Metamorphosed Belt Supergroup[1]
Conifer forest (ton/acre/year)	0.023	0.032
Non-stocked forest and waste rock piles (tons/acre/year)	0.027	0.040
Double wildfire burn (ton/acre/year)	0.004	0.006
Roads (tons/acre/year)	0.019	0.026

[1] Based on export coefficients provided for West Fork St. Maries River and Cats Spur Creek.

Sedimentation Estimates

Sedimentation estimates were developed by addition of the various sediment yields prorated for delivery to the channels (Table 19). Copies of the Excel? model spreadsheets are available in Appendix D.

Sediment model results (Table 19) indicate that several tributaries to the St. Maries River and its two forks exceed background sediment yield by greater than 50%. Sediment yield greater than 50% above background is used as a coarse filter to segregate streams in which sediment may be impairing water quality (Washington Forest Practices Board 1995). Santa and Carpenter Creeks and the St. Maries River and its West and Middle Forks exceed sediment yield thresholds (Tables 19a and b). Emerald, Tyson, and Merry Creeks may have sediment yields in a range that causes water quality impairment.

Table 19. Estimated sediment delivery to the St. Maries River Subbasin.

a) Estimated sediment delivery of the west-side tributaries to the St. Maries River[1]

Status of Beneficial Uses

Nutrients were found to be at non-nuisance levels in Gold Center Creek, Santa Creek, Thorn Creek, Alder Creek, and the St. Maries River. The dissolved oxygen concentration is not limiting in Santa Creek.

Temperature standards are exceeded for significant periods in Gramp, Gold Center, Flewsie, Emerald, and Santa Creeks. The West and Middle Forks of the St. Maries River also exceed temperature standards for significant periods. The main stem of the St. Maries River likely exceeds the standards for significant periods. The unknown pollutant of the St. Maries River is likely temperature. Bacteria are not limiting Gramp Creek.

Sediment model results indicate that streams supporting their fishery uses are in a range of zero to 50% above background sediment yield. Santa and Carpenter Creeks, the West and Middle Forks, and the St. Maries River exceed this threshold and are sediment impaired. Emerald, Tyson, and Alder Creeks may exceed the threshold as well. Modeling suggests that stream bank erosion is the primary source of sediment. This sediment is primarily coarse sand that fills pools in the streams. Since the St. Maries River segments are impaired by sediment, a TMDL that addresses sediment in the entire St. Maries River Subbasin will be required. The assessed support status of the listed water bodies based on available data is provided in Table 20.

Table 20. Results of the St. Maries River Subbasin assessment based on application of the available data.

Waterbody Name and HUC Number	Assessed Support Status	Reasons Segment is to be De-listed for Pollutant
St. Maries River 17010304 3579 17010304 3580	Sediment modeling and WBAGII[1] scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required; Nutrient monitoring indicates levels within guidelines, delist for nutrients; Temperature standard exceeded, temperature TMDL required.	Monitoring of total phosphorous, nitrite-nitrate, and total nitrogen indicates concentrations during critical summer months below nuisance weed growth guidelines. Periphyton sampling results reveal biomass below nuisance levels[2].
West Fork of the St. Maries River 17010304 3581	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL; Temperature standard exceeded, temperature TMDL required.	N/A
Middle Fork of the St. Maries River 17010304 3594	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL; Temperature standard exceeded, temperature TMDL required.	N/A
Thorn Creek 17010304 3582	Nutrient monitoring indicates levels within guidelines, delist for nutrients. Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required; included subbasin-wide sediment TMDL.	Monitoring of total phosphorous, nitrite-nitrate, and total nitrogen indicates concentrations during critical summer months below nuisance weed growth guidelines. Periphyton sampling results reveal biomass below nuisance levels.
Alder Creek 17010304 3583	Nutrient monitoring indicates levels within guidelines; Sediment modeling and WBAGII scores indicate cold water may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	Monitoring of total phosphorous, nitrite-nitrate, and total nitrogen indicates concentrations during critical summer months below nuisance weed growth guidelines[2]. Periphyton sampling results reveal biomass below nuisance levels.
John Creek 17010304 3584	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	N/A
Santa Creek 17010304 3585	D.O.[3] standard supported, delist for D.O.; Nutrient monitoring indicates levels within guidelines, delist for nutrients; Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL; Temperature standard exceeded, temperature TMDL required.	D.O. above cold water aquatic life standard (Table 9); Monitoring of total phosphorous, nitrite-nitrate, and total nitrogen indicates concentrations during critical summer months below nuisance weed growth guidelines. Periphyton sampling results reveal biomass below nuisance levels.
Charlie Creek 17010304 3587	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	N/A
Renfro Creek 17010304 3588	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	N/A
Tyson Creek 17010304 3589	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	N/A
Crystal Creek 17010304 3590	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	N/A
Carpenter Creek 17010304 3591	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL.	N/A
Emerald Creek 17010304 3593	Sediment modeling and WBAGII scores indicate cold water aquatic life may not be supported by sediment levels, sediment TMDL required, included in subbasin-wide sediment TMDL; Temperature standard exceeded, temperature TMDL required.	N/A

Table 20, continued.

Waterbody Name and HUC Number	Assessed Support Status	Reasons Segment is to be De-listed for Pollutant
Gold Center Creek 17010304 3596	Temperature standard exceeded, temperature TMDL required. Sediment modeling and WBAGII scores indicate cold water aquatic life supported by sediment levels, sediment TMDL is not required.	Sediment modeling and WBAGII scores indicate cold water aquatic life is supported by sediment levels.
Flewsie Creek 17010304 3596	Temperature standard exceeded, temperature TMDL required. Sediment modeling and WBAGII scores indicate cold water aquatic life supported by sediment levels, sediment TMDL is not required.	Sediment modeling and WBAGII scores indicate cold water aquatic life is supported by sediment levels.
Gramp Creek 17010304 3598	Monitoring of bacteria indicates full support of contact recreation, delist for bacteria. Temperature standard exceeded, temperature TMDL required. Sediment modeling and WBAGII scores indicate cold water aquatic life supported by sediment levels, sediment TMDL is not required.	Monitoring of *E.coli* indicates full support of contact recreation standard (Table 12). Sediment modeling and WBAGII scores indicate cold water aquatic life is supported by sediment levels.

[1]*Water Body Assessment Guidance*, Version II.
[2]IDAPA 58.01.02.05-06; According to the EPA's *Rapid Bioassessment Protocols for Use in Wadeable Streams and Rivers* (1999), levels of algal biomass greater than 10 µg chlorophyll *a* cm^2 or greater than 5 mg ash-free dry mass (AFDM) cm^2 indicate nuisance levels of nutrients or organic enrichment.
[3]Dissolved oxygen.

Conclusions

The TMDLs currently required in the St. Maries Subbasin are listed in Table 21.

Table 21. TMDLs required for the St. Maries River Subbasin and general specifications.

Waterbody	TMDL Required	Critical flow	Boundaries of Exceedence	Critical Reaches	Key indicator
St. Maries River[1]	Sediment	Episodic high flow	Entire watershed, including all tributaries	Rosgen B and C channels	Tons/year
St. Maries River	Temperature	Low summer flow	Main stem Clarkia to Mouth	Main stem Clarkia to mouth	Full potential shade
West Fork St. Maries River	Temperature	Low summer flow	Headwaters to St. Maries River	Entire length	Full potential shade
Middle Fork St. Maries River	Temperature	Low summer flow	Headwaters to St. Maries River	Entire length	Full potential shade
Santa Creek	Temperature	Low summer flow	Headwaters to St. Maries River	Entire length	Full potential shade
Emerald Creek	Temperature	Low summer flow	Headwaters to St. Maries River	Entire length	Full potential shade
Gold Center Creek	Temperature	Low summer flow	Headwaters to St. Maries River	Entire length	Full potential shade
Flewsie Creek	Temperature	Low summer flow	Headwaters to St. Maries River	Entire length	Full potential shade
Gramp Creek	Temperature	Low summer flow	Headwaters to Gold Center Creek	Entire length	Full potential shade

[1]Since the lowest reach of the St. Maries River is water quality limited due to sediment, the sediment TMDL covers the entire subbasin, regardless of individual streams' listing status.

2.4 Data Gaps

Additional CWE data or data from an equivalent procedure for Cats Spur, Emerald, and Flewsie Creeks would be supportive of the sediment modeling and temperature TMDLs.

Additional temperature data are required for all the segments of the subbasin. Spatial temperature data would better improve the scope of temperature exceedences.

3. Subbasin Assessment – Pollutant Source Inventory

Several sources of sediment exist in the St. Maries River watershed, including natural sediment loads. All significant sources of sediment are nonpoint sources. Sources of thermal input are restricted to loss of stream canopy cover.

3.1 Sources of Pollutants of Concern

Pollutant sources of sediment are discussed in the following sections. Sediment is contributed to the subbasin by a large number of sources, including natural erosion.

Point Sources

Point sources of sediment include the Santa-Fernwood, Emida, and Clarkia wastewater treatment facilities. These facilities have TSS limits of 30 mg/L. They may potentially discharge 14.1 tons per year, which is 0.10% of the modeled sediment load (Table 19c). Since these dischargers do not often approach their discharge limits, the sediment estimate for these sources is likely liberal. Compared to sediment loads modeled, actual point source loads are very small.

There are three thermal point sources present in the subbasin including the Santa-Fernwood, Emida, and Clarkia wastewater treatment facilities. There are no power or manufacturing plant cooling water facilities.

There are no Superfund or Resource Conservation Recovery Act sites in the subbasin. Petroleum spills have been addressed at three locations in the subbasin.

Nonpoint Sources

The primary disturbances causing stream temperatures to rise is non-natural canopy modification by placer mining for garnets and silvicultural and agricultural practices. The attainment of natural full potential canopy shade is the most that can be done to lower stream temperatures.

Nonpoint sources of sediment include placer mining for garnets, silvicultural practices (especially forest roads), agriculture, and stream bank erosion triggered by grazing or in-stream effects. The majority of the land use in the subbasin is forestland (Figure 6). Agricultural and silvicultural features such as road crossings and encroaching roads are accounted for in the sediment model (Appendix C) and are documented in the GIS coverages that were used to load the model.

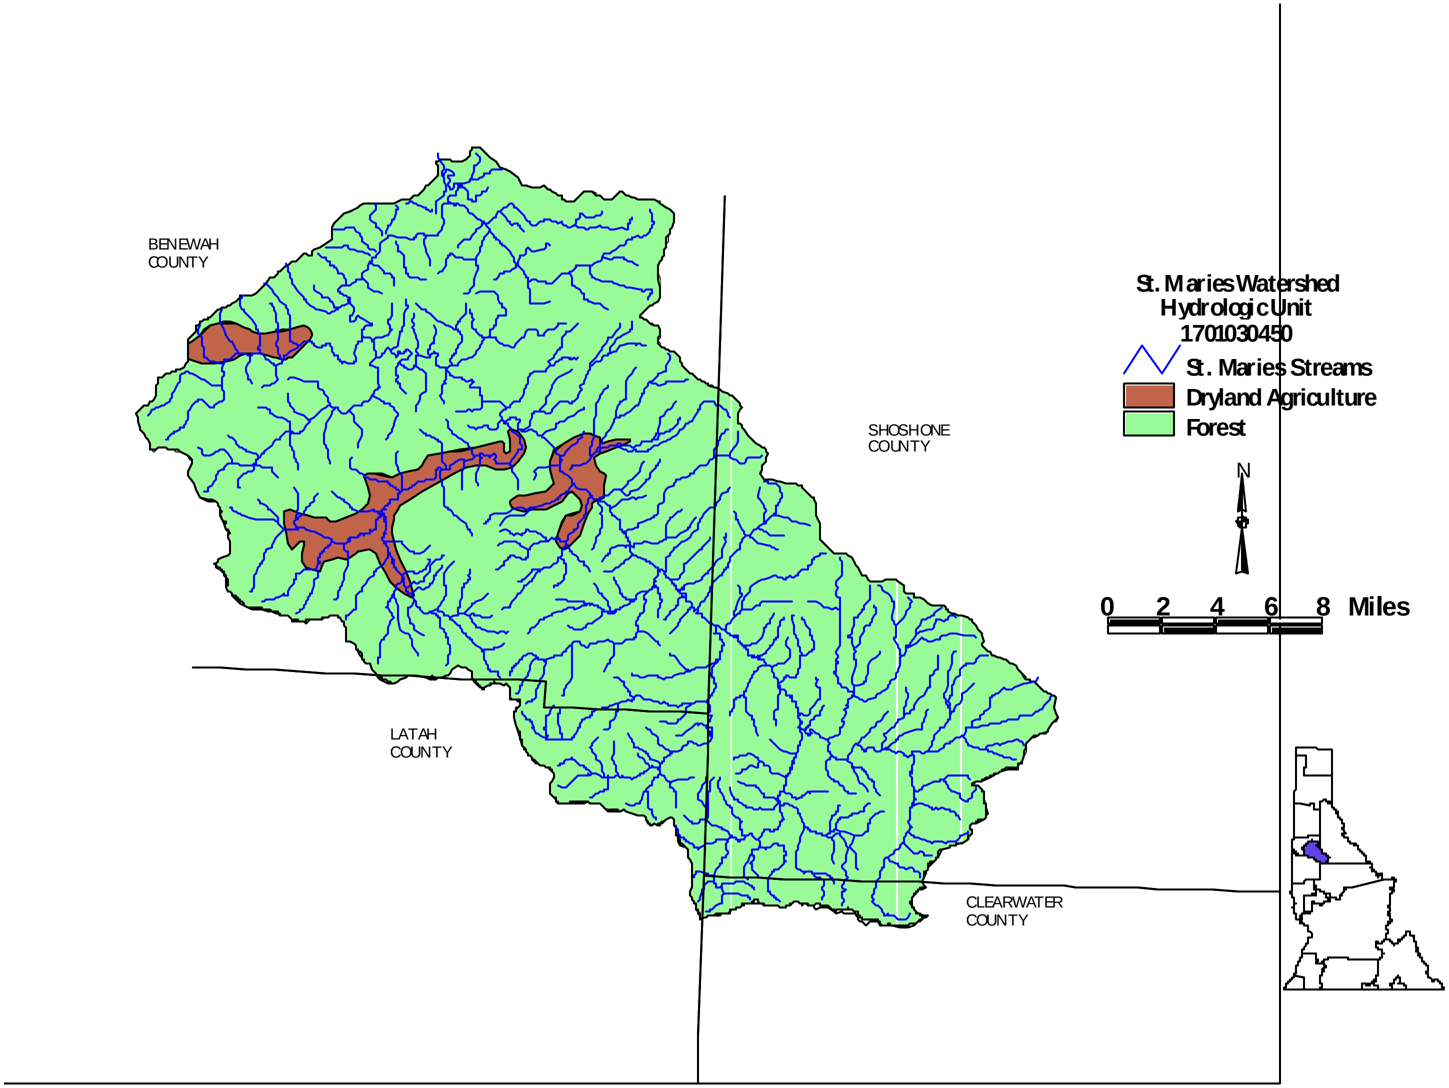

Figure 6. St. Maries Subbasin Land Use

Sediment sources can be described by land use category as follows:

-- The meta-sedimentary rocks of the Proterozoic Belt Supergroup and bed rock, as altered by extreme heat, form a terrain with a natural sediment yield rate of 0.026 – 0.040 tons per acre per year (17 – 26 tons per year per square mile). Mass wasting is not a typical feature of the terrain; however, it does occur on the lacustrine deposits of the late Eocene Lake bed in the vicinity of Clarkia and Miocene Lake Coeur d'Alene deposits. Mass wasting is directly estimated in the CWE process.

-- Timber harvest is a source of sediment, especially in the first year following the harvest when the cut area is void of cover. Forest ground cover regenerates rapidly in open areas where new plants are not competing with mature trees. Ground cover has been observed to return to 28-50% cover the first year after a harvest and near 75% in year two (Elliot and Robichaud 2001). Once vegetative cover is re-established to pre-harvest conditions, excess sedimentation associated with the harvest does not occur.

-- Timber harvest roads are a significant source of sediment. These can yield surface sediment, trigger mass wasting, constrain streams, and accelerate erosion. County and state roads, railroads, and highways can also constrain streams and accelerate erosion.

-- Stream bank erosion was assessed throughout the subbasin by the direct delivery method. Model results indicated that bank erosion was a significant source of sediment yield.

-- Placer-mined lands are a sediment source. Large areas of the Emerald and Carpenter Creek watersheds have been placer-mined for garnet. The relief of the mined areas is low, minimizing sediment yield from mined-over lands. Current surface mining best management practices also minimize erosion. However, raw banks are left from past mining and contribute to sediment yield. Hydraulic mining of gold occurred in Tyson Creek (Russell 1979). This activity occurred well before any surface mining rules or best management practices were in place.

Pollutant Transport

Pollutant transport is relevant only to sediment. Sediment is delivered to the stream system primarily during high precipitation/high discharge events or rapid snowmelt events. These are episodic events. Under these conditions, large volumes of sediment move in the stream systems. These conditions develop stream power and stage heights capable of channel alteration. Sediment trapped in upper low order watersheds moves quickly to the higher order streams of the subbasin. Areas where the stream gradient is constrained by roads have rapid erosion from bed and/or banks. The gradient of the St. Maries River and its two forks is insufficient to flush sediment larger than coarse sand from the stream channel. Coarse sand makes up a substantial percentage of the bed sediments found in the river. A sediment transport model is not available for the St. Maries River.

3.2 Data Gaps

The major data gap in temperature pollution is monitoring data from the entire length of the stream. The major data gap in sediment pollution stems from a lack of in-stream measurements of load and transport of sediment.

Point Sources

Point discharges of sediment have been identified in the subbasin. Three possible point discharges of heat have been documented, including the Santa-Fernwood, Emida, and Clarkia wastewater treatment facilities.

Nonpoint Sources

Nonpoint sources have been modeled rather than measured. In-stream monitoring of sediment load would be of value. Such monitoring is quite expensive (see Section 2.3, page 26), and is unlikely that this data gap will be filled. Model results continue to be the best available information at this time.

Current temperature data was collected through in-stream monitoring at set locations. Thermal imaging that provides a view of stream-wide temperatures would be of value, but is costly.

4. Subbasin Assessment – Summary of Past and Present Pollution Control Efforts

The wastewater point sources associated with community wastewater treatment in the watershed (Santa-Fernwood, Emida, and Clarkia wastewater treatment facilities) were permitted under NPDES during the 1970s. These permits were renewed last in 1988 and 1989. Renewal of these permits is currently underway.

All forest practices conducted in the subbasin are regulated under the Idaho Forest Practices Act rules and regulations. These rules are in part best management practices designed to abate erosion and retard sediment delivery to the streams. All USFS harvests must meet inland fish strategy (INFISH) guidelines. These guidelines prescribe 300 foot-wide buffers for streams with fishery uses. The USFS has relocated and obliterated approximately 55 road miles removing 187 stream crossings by roads from the subbasin (Patten 2002).

Most agricultural practices in the subbasin consist of livestock grazing and some hay harvesting. The USFS has installed riparian fencing to exclude 66 acres of its grazing allotments and planted these with riparian trees and shrubs (Patten 2002). The Benewah Soil and Water Conservation District has completed a stream bank erosion analysis on Santa Creek. The district has secured CWA Section 319 funding for additional riparian zone exclusion fencing and bank stabilization work, which was implemented during summer 2002.

The garnet mining operation in the subbasin has been brought under the Idaho Placer and Dredge Mining Rules and Regulations (IDAPA 16.01.02.350.03(f)). The operators have restored 3.7 miles of stream channels and have reclaimed 203 acres of mined floodplain lands.

These actions have been site- and project-specific. The actions are relatively few on a basin-wide perspective. None of these actions are part of an integrated program. It is unlikely that water quality will improve to a level of full beneficial use with current water quality improvement actions.

5. Total Maximum Daily Loads

A TMDL sets an upper limit on discharge of a pollutant from all sources so as to assure water quality standards are met. It further allocates this load capacity (LC) among the various sources of the pollutant. Pollutant sources fall into two broad classes: point sources, each of which receives a wasteload allocation (WLA); and nonpoint sources, which receive a load allocation (LA). Natural background (NB), when present, is considered part of the LA, but is often broken out on its own because it represents a part of the load not subject to control. Because of uncertainties regarding quantification of loads and the relation of specific loads to attainment of water quality standards, the rules regarding TMDLs (40 CFR, Part 130) require a margin of safety (MOS) be a part of the TMDL.

Practically, the margin of safety is a reduction in the load capacity that is available for allocation to pollutant sources. The natural background load is also effectively a reduction in the load capacity available for allocation to human made pollutant sources. This can be summarized symbolically as the equation: LC = MOS + NB + LA + WLA = TMDL. The equation is written in this order because it represents the logical order in which a loading analysis is conducted. First the LC is determined. Then the LC is broken down into its components: the necessary MOS is determined and subtracted; then NB, if relevant, is quantified and subtracted; and then the remainder is allocated among pollutant sources. When the breakdown and allocation are complete we have a TMDL, which must equal the LC.

Another step in a loading analysis is the quantification of current pollutant loads by source. This allows the specification of load reductions as percentages from current conditions, considers equities in load reduction responsibility, and is necessary in order for pollutant trading to occur. Also a required part of the loading analysis is that the LC be based on critical conditions – the conditions when water quality standards are most likely to be violated. If protective under critical conditions, a TMDL will be more than protective under other conditions. Because both LC and pollutant source loads vary, and not necessarily in concert, determination of critical conditions can be more complicated than it may appear on the surface.

A load is fundamentally a quantity of a pollutant discharged over some period of time, and is the product of concentration and flow. Due to the diverse nature of various pollutants, and the difficulty of strictly dealing with loads, the federal rules allow for "other appropriate measures" to be used when necessary. These "other measures" must still be quantifiable, and relate to water quality standards, but they allow flexibility to deal with pollutant loading in more practical and tangible ways. The rules also recognize the particular difficulty of quantifying nonpoint loads, and allow "gross allotment" as a load allocation where available data or appropriate predictive techniques limit more accurate estimates. For certain pollutants whose effects are long term, such as sediment and nutrients, EPA allows for seasonal or annual loads.

Some streams in the St. Maries River subbasin are impaired due to habitat alteration. While degraded habitat is evidence of impairment, the EPA does not consider a waterbody to be polluted if the pollution is not a result of the introduction or presence of a pollutant. Since TMDLs are not required to be established for waterbodies impaired by pollution but not pollutants, a TMDL has not been established for these streams for habitat alteration.

5.1 St. Maries River Sediment TMDL

This TMDL addresses the St. Maries River. Since the lowest reach of the St. Maries River is water quality limited due to sediment, the sediment TMDL covers the entire subbasin, regardless of individual streams' listing status.

5.1.1 In-Stream Water Quality Target

The in-stream water quality target for the St. Maries River sediment TMDL is full support of cold water aquatic life and salmonid spawning (Idaho Code 39.3611, 3615). The TMDL will develop loading capacities in terms of mass per unit time. The interim goals are for sub-watersheds to support cold water aquatic life and the final goal is for bio-monitoring to reveal full support of cold water aquatic life throughout the subbasin and salmonid spawning where that use is either designated or existing. The sources yielding sediment to the system can be reduced, but a substantial period (30-50 years) will be required for the stream to clear its current coarse sand sediment bed load and to create pools.

Design Conditions

The predominant sources of sediment to the St. Maries River and its tributaries are nonpoint sources. Three minor point sources discharge suspended solids. The TMDL addresses the point and nonpoint sediment yields within the watershed. Sediment from the point source discharges is loaded on a rather constant basis, while sediment from nonpoint sources is loaded episodically, primarily during high discharge events. These critical events coincide with critical conditions and occur during the November through May period. However, they may not occur for several years. The critical stream reaches are the Rosgen B channel types that naturally harbor the most robust cold water communities, but have gradients sufficiently low for coarse sand bedload to accumulate and fill pools. The return time of the largest events is 10-15 years (DEQ 2001). The key to nonpoint source sediment management is implementing remedial activities prior to the advent of a large discharge event. Once sediment is loaded into the stream, large discharge events are required to transport coarse sediments downstream.

Target Selection

The TMDL applies sediment allocations in tons per year and calculates sediment reduction goals. Several tributaries, the Middle Fork, the West Fork, and the St. Maries River were listed as impaired by sediment in 1998 (Table 21). Sediment yield reduction will be required from the entire watershed in order for the impaired watersheds to meet full support status.

The load capacity rate at which full support is exhibited has been set at various levels within TMDL documents developed by DEQ. These have ranged from setting an interim load capacity at the background level for some watersheds in the Coeur d'Alene Lake subbasin and the Pend Oreille basin, to over 200% above background in some areas of the state. Evidence is beginning to support that a target of 50% above background is protective of the beneficial uses. This target has already been used in the North Fork Coeur d'Alene TMDL (DEQ 2001) and the Priest River TMDL (Rothrock 2002). The rationale supplied in those TMDLs in support of the target was based on several premises (DEQ 2001).

-- Sediment yield below 50% above background will fully support the beneficial uses of cold water aquatic life and salmonid spawning,

-- The stream has some finite yet not quantified ability to process a sediment yield rate greater than 50% above background rates, and

-- Beneficial uses (cold water aquatic life and salmonid spawning) will be fully supported when the finite yet not quantified ability of the stream system to process (attenuate) sediment is met.

Data collected within the St. Joe and St. Maries Subbasins appear to support the target of 50% above background. A comparison of WBAGII scores of watersheds to modeled percent above background estimates is shown in Figure 7. Only watersheds that had WBAGII scores based on all three of the major components (macroinvertebrates, fish, and habitat) were included in the analysis. The green shaded area indicates the area of the graph where both the WBAG II score is full support and the modeled percent above background is less than 50%. The red area is the portion of the graph where the WBAGII scores shows that a stream is impaired and the modeled percent above background is greater than 50%. In all but two instances the WBAGII score and the target of 50% above background agree. The two watersheds that do not conform may be affected by conditions other than sediment and are therefore unresponsive to changes in sediment delivery to the stream. For instance, the St. Joe River's Blackjack Creek has a WBAGII score of less than 2, but has very little sediment being delivered to it. This is a first order watershed that is very small with a steep gradient. The low WBAG II scores are a result of poor macroinvertebrates and fish populations. The creek's habitat score was one of the highest in the subbasin. The poor macroinvertebrate score could be result of the small watershed size and relatively little disturbance making the system nutrient poor and therefore unable to support a good macroinvertebrate community. This low nutrient scenario could also affect the fish community due to a poor food base. The fish community may also be affected by the steep gradient of this watershed, which could make available fish habitat limited.

As such, the 50% above background target appears to be reasonable and very protective of the beneficial uses of the watersheds in the St. Joe and St. Maries Subbasins. Therefore, the target load capacity for the St. Maries River TMDL has been set at 50% above background.

The goal should be attained following three high flow events after implementation plan actions are in place. On average, three events occur every 50 years. This time is necessary to have the channel forming events to export sediment and to create pool structures.

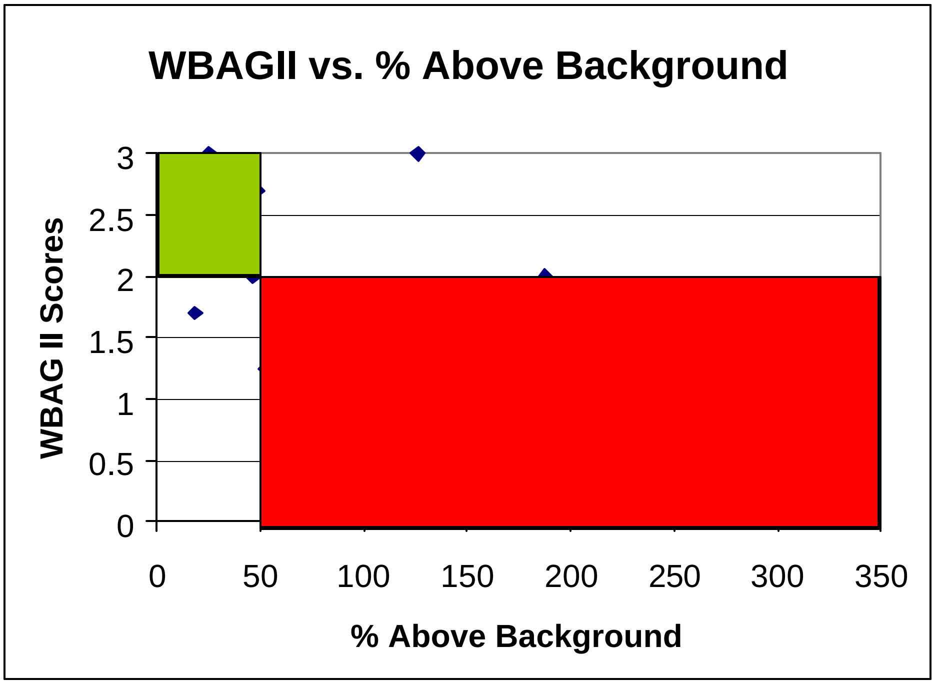

Figure 7. WBAGII Scores Versus Percent Above Background

<u>Monitoring Points</u>

Ten points of compliance are set. These are: the Middle Fork near the mouth (BURP site # 1996SCDAA040); the West Fork near the mouth (BURP site # 1998SCDAA021); Emerald Creek near the mouth (BURP site # 1995SCDAB008); the St. Maries River at Emerald Creek (BURP site # 1997SCDAA033); Carpenter Creek near the mouth (BURP site # 1995SCDAB054); the St. Maries River at Tyson Creek (BURP site to be established); Tyson Creek near the mouth (BURP site # 1995SCDAB055); Santa Creek near the mouth (BURP Site # 1995SCDAB005) Alder Creek near the mouth (BURP Site # 1995SCDAB004); and the St. Maries River below Thorn Creek (BURP Site to be established). Sediment load reduction from current levels toward the sediment yield reduction goal of 50% above background is expected to attain a sediment load that is not yet quantified, but will fully support the cold water beneficial use.

Beneficial use support status will be determined using the current assessment method accepted by DEQ at the time the waterbody is monitored. Monitoring will be completed using BURP protocols. When the final sediment load capacity is determined by these appropriate measures of full cold water aquatic life support, the TMDL will be revised to reflect the established supporting sediment yield.

5.1.2 Load Capacity

The load capacity for a TMDL designed to address a sediment-caused limitation to water quality is complicated by the fact that the state's water quality standard a narrative rather than quantitative. In the waters of the St. Maries River, the sediment interfering with the beneficial use (cold water) is most likely coarse sand bed load particles. Adequate quantitative measurements of the effect of excess sediment have not been developed. Given this difficulty, an exact sediment load capacity for the TMDL is difficult to develop.

The natural background sedimentation rate is the sediment yield prior to human development of the watershed. It was calculated by multiplying the watershed acreage by the appropriate sediment yield coefficient (0.023 tons/acre/year) for Belt Supergroup terrain vegetated by coniferous forests and 0.032 tons/acre/year) for watersheds with predominantly metamorphosed Belt Supergroup terrain. The estimate assumes the entire watershed was vegetated by coniferous forest prior to development. The calculated estimated natural background sediment yield values for the subbasins of the St. Maries River are provided in Table 22, as are the 50% above background sediment yield goals. The goals are estimated goals that will be replaced by the final sediment goal when the criteria for full support of cold water aquatic life are met. The load capacity based on the projected goal at the point of compliance is provided in Table 22. Loading capacities were developed by calculating background sedimentation based on acreage above the point of compliance, then adding an additional 50% to the value.

Critical Conditions

Critical conditions are part of the analysis of load capacity. The beneficial uses in this subbasin are impaired due to chronic sediment conditions. Due to the chronic condition, this TMDL deals with yearly sediment loads. The concept of critical conditions is difficult to reconcile with the impact caused by sediment. The critical condition concept assumes that under certain conditions, chronic pollution problems become acute pollution problems and therefore we need to ensure that acute conditions do not occur. The proposed sediment reductions in the TMDL will reduce the chronic sediment load and also reduce the likelihood that an acute sediment loading condition will exist. It is in this way that we have accounted for critical conditions in the TMDL.

Table 22. St. Maries River sediment background and load capacity at the points of compliance.

Location	Acreage of watershed	Background (tons/year)	Load capacity at 50% above background (tons/year)
Middle Fork St. Maries River	43,316	996	1,494
West Fork St. Maries River	23,654	757	1,136
Emerald Creek	23,239	744	1,116
St. Maries River at Emerald Creek	103,912	2,390	3,585
Carpenter Creek	12,857	296	444
St. Maries River at Tyson Creek	150,102	3,452	5,178
Tyson Creek	8,042	185	278
Santa Creek	47,212	1,086	1,629
Alder Creek	15,875	365	548
St. Maries River below Thorn Creek	307,485	7,072	10,608

5.1.3 Estimates of Existing Pollutant Loads

Point sources of sediment are from the three permitted wastewater treatment facilities (Table 16). As stated in Section 2.3, the point sources at maximum permitted discharge account for 14.1 tons per year of fine sediment. This amount is potentially 0.10% of the load. The point sources are not a significant source of sediment and will be allocated their existing loads.

Nonpoint sources of sediment yield were estimated in Section 2.3 (Tables 19a-c). These estimates were made using the assumptions and model approach fully documented in Appendix C. The model spreadsheets are provided in Appendix D. Loading rates are based on land use and road impacts (see Section 2.3, Tables 17a-c, and Appendices B and C). Estimated sediment loads from the watersheds above the points of compliance are shown in Table 23.

The sediment loading occurs as a result of forestland activities, agricultural land activities and stream bank erosion. Stream bank erosion is the single largest source of sediment in the watershed. The estimated current percentage of sediment delivery by the acres of land holdings is provided in Table 24.

Table 23. St. Maries River and tributary sediment loads from nonpoint sources in St. Maries River watershed.

Load Type	Location	Estimated Existing Load (tons/year)	Background (tons/year)	Percent Over Background (%)	Estimation Method
Sediment	Middle Fork of the St. Maries River	1,610	996	62	Model

5.1.4 Sediment Load Allocation and Wasteload Allocation

The sediment allocation is equal to the load capacity minus the margin of safety and background. It is comprised of the wasteload allocation of point sources and the load allocation of nonpoint sources.

Margin of Safety

A margin of safety is implicit in the model used. The model is estimated to be 231% conservative when applied on Belt terrain and 164% conservative on metamorphosed Border Belt terrain (Appendix C). This level of conservative assumptions provides an over-estimation of sediment yield. The over-estimation is the implicit margin of safety. Given the conservatively high estimations developed by the model, no additional explicit margin of safety is deemed necessary.

Seasonal Variation

Sediment from nonpoint sources is not loaded seasonally. It is loaded episodically, primarily during high discharge events. These critical events coincide with the critical conditions and occur during November through May. However, they may not occur for several years. The return time of the largest events is 10-15 years (DEQ 2001).

Reasonable Assurance of TMDL Implementation

The sediment model identifies stream bank erosion and forest roads as primary sources of sediment in the subbasin. The federal government and IDL manage land in the subbasin. IDL has been directed by a gubernatorial executive order to directly implement state developed TMDLs on lands that they manage directly or to oversee implementation of the Forest Practices Act. Federal ownership and executive order should assure that implementation plans are developed for forest roads. A plan will be implemented for roads based primarily on the budgetary constraints of the federal and state agencies. Most eroding banks are on private land. Incentives provided to private landowners by the Benewah Soil and Water Conservation District might be necessary to address these eroding banks.

Background

Sediment background levels for the watersheds are shown above in Table 23. The backgrounds are allocated as part of the load capacity. Any unknown, unallocated point sources are included in the background portion of the allocation.

Reserve

No part of the load allocation is held for additional load. Any new infrastructure should be constructed or mitigated to allow no net increase in sediment yield to the watersheds.

Remaining Available Load

There is no remaining available load.

Wasteload Allocation

Sediment contribution from point sources is 0.10% of that estimated for the watershed. Since the contribution from point sources is negligible, the wasteload is set at current permit limits. These are provided below in Table 25.

Table 25. Wasteload allocation to the permitted point discharges of the St. Maries River Subbasin.

Permitted Discharge	Average Discharge (million gallons/day)	Total Suspended Solids Limit (mg/L)	Maximum Daily Sediment Load (pounds/day)	Maximum Annual Load (tons/year)
Santa-Fernwood	0.2	30	34.0	6.2
Emida	0.15	30	37.5	6.8
Clarkia	0.15	30	6.0	1.1
Total	0.5	-	77.5	14.1

Load Allocation

Load allocations required at the points of compliance are shown in Tables 26a-j. The allocation is based on a reduction to 50% above background and on the modeled estimate of nonpoint source sediment contribution in tons per year. The margin of safety is applied to the allocations at the points of compliance. The allocation includes background sediment yield. After implementation, the main channels of the tributaries and the St. Maries River are provided a 50-year time frame for meeting the allocations. This time frame allows for three large channel forming events to occur in the stream.

Table 26. Sediment load allocation and load reduction required at the points of compliance on the St. Maries River and its tributaries.

a) Middle Fork of the St. Maries River allocation

Source	Percentage of load source	Load allocation (tons/year)	Load reduction required (tons/year)	Time frame for meeting allocations
U.S. Forest Service	27.5	411	32	50 years
Idaho Dept. of Lands	8.3	124	10	50 years

Monitoring Provisions

In-stream monitoring of beneficial use (cold water and salmonid spawning) support status during and after implementation of sediment abatement projects will establish the final sediment load reduction required by the TMDL. In-stream monitoring, which will determine if the threshold values identified in Section 5.1.1 (page 60) have been met, will be completed every year on a randomly selected 1% of the watershed's Rosgen B channel types. Independent monitoring parameters will be developed for the St. Maries River monitoring stations. Monitoring will assess stream reaches in length of at least 30 times bank full width. These reaches will be randomly selected from the total B type stream channels until at least

5% of these channels have been assessed after five years. Identical measurements will be made in appropriate reference streams where beneficial uses are supported. Data will be compiled after five years. The yearly increments of random testing that sum to 5% of the stream after five years should provide a database not biased by transit fish and macroinvertebrate population shifts. Based on this database the beneficial use support status will be determined.

Feedback Provisions

When beneficial use support meets the full attainment level, further sediment load reducing activities will not be required in the watershed. At that time a revised TMDL with an ambient sediment load will be developed. Best management practices for forest and surface mining operations will be prescribed by the revised TMDL with provisions to maintain erosion abatement structures. Regular monitoring of the beneficial uses will continue for an appropriate period to document maintenance of the full support of the use.

5.1.5 Conclusions

St. Maries River Subbasin assessment has revealed an array of fisheries, residual pool volume, and sediment modeling results that show the that the St. Maries River and several of its tributaries have sediment impairment of the cold water aquatic life.

A sediment TMDL was prepared for the entire St. Maries River watershed. The TMDL set a goal of 50% above natural background sediment yield based on an agreement between DEQ and EPA that recognizes the presence of watersheds fully supporting cold water beneficial use at levels well above natural background. The loading capacities were set for several points of compliance based on this goal. The load capacity was allocated on a gross land owner/manager basis. An implicit margin of safety of 231% was applied in the sediment model. Point sources of sediment are very minor (0.10%) and are negligible compared to the nonpoint sediment sources. The wasteload allocation was set at the level of the current NPDES permits for suspended solids.

5.2 St. Maries River Temperature TMDL

This TMDL addresses the St. Maries River and its tributaries that have been listed as water quality limited by temperature, including Gramp, Gold Center, Flewsie, Emerald, and Santa Creeks and the Middle and West Forks of the St. Maries River.

5.2.1 In-Stream Water Quality Targets

Neither the St. Maries River nor any of its tributaries listed for temperature are in the St. Joe bull trout recovery area (St. Joe River headwaters to Mica Creek) (Panhandle Bull Trout Technical Advisory Team 1998). The governing temperature standard for the watershed is Idaho's 9 ^{o}C daily maximum spawning standard from May through June. Prior to May, water temperature is expected to be well below 9 ^{o}C in the St. Joe Subbasin. In practice, the 10 ^{o}C seven-day running average from May 1 to September 1 and the state 9 ^{o}C daily maximum spawning standard are essentially the same (Dupont 2002). Monitoring of temperature in St.

Joe Subbasin streams with little or no human development and at relatively high elevation indicate that this standard is not attainable throughout the entire St. Joe Subbasin, including the St. Maries River (Table 12). Temperature assessments of Gramp, Gold Center, Flewsie, and Emerald Creeks and the Middle Fork of the St. Maries River indicates significant exceedences of the state salmonid spawning standards (Table 11; Appendix B). Similar exceedences are expected for the St. Maries River, West Fork of the St. Maries River, and Santa Creek. It is currently beyond technical ability to assess the sufficiency of cold water habitat during the late spring and early summer months.

Design Conditions

Stream temperature is affected by natural weather conditions and adjacent plant community potential, including disturbance and recovery. Vegetation manipulation to create access or as a result of timber harvest is the major anthropogenic cause of increased stream temperatures.

The environmental factors affecting stream temperature are local air temperature, stream depth, ground water inflow, and stream shading by riparian cover and/or topography (Sullivan and Adams 1990, Theurer *et al.* 1984, Beschta and Weatherred 1984). Topographic elevation affects ambient air temperature. Higher elevations have lower ambient air temperatures. In forest streams, ambient temperature and shading are believed to account for up to 90% of the stream temperature variability (Brown 1971). Of these two factors, riparian shade is the only one that can be modified by management.

Several models can be used to assess the impact of riparian shade on stream temperature. Heat Source (Boyd 1996) and the USGS Stream Segment Temperature Model (SSTEMP) (Theuer *et al.* 1984, Bartholow 1989) quantify the energy transfer mechanisms in streams. These models require extensive data inputs, many of which are not available for mountain streams. The use of process-based models was found a workable approach for the Upper North Fork Clearwater Temperature TMDLs (Dechert *et al.* 2001). It uses the IDL CWE Canopy Closure-Stream Temperature protocol. Energy loading values are developed using SSTEMP results as comparative data to the primary TMDL target measurement of percent canopy cover.

The CWE empirical model is based on continuous stream temperature measurements, topographic elevation, and the percent of vegetative canopy cover data collected throughout northern Idaho. The model calculation is as follows:

Equation (1) $$MWMT = 29.1 - 0.00262*E - 0.0849*C$$

where MWMT = maximum weekly maximum temperature (^{o}C)
E = stream reach elevation (feet)
C = riparian canopy cover (%)

The equation can be solved for canopy cover to predict the required canopy at a given elevation.

Equation (2) $$C = (29.1/0.085) - (MWMT/0.085) - (E * 0.0026/0.085)$$

To calculate required canopy cover for the water bodies, MWMT would be set at $10^{o}C$.

$$\text{Equation (3)} \quad C = 224.7 - 0.031 * E$$

To satisfy the requirement for an analysis of heat loading (energy per unit area per unit time) to a stream due to insolation, the method of Dechert *et al.* (2001) was used. The approach uses SSTEMP (Bartholow 1997) to derive data for August 1, 2000 (median hottest day), for insolation rates and calculates heat loading for different levels of percent shade. The amount of solar radiation incident on a stream and its immediate surroundings at different shade levels for three non-redundant stream orientations are presented in Table 27. The fixed conditions used in SSTEMP to develop the solar radiation numbers, in this case for the Upper North Fork Clearwater River, were 47? north latitude, 5,000 feet elevation, 10 foot stream width, 60 foot buffer height, 30 foot buffer width, and 30? topographic shade (Dechert *et al.* 2001). Under these conditions, incident solar radiation decreases regularly by 21 watts per square meter for every 10% increase in canopy density for north-south oriented streams and 26 watts per square meter for east-west oriented streams. The St. Maries Subbasin is near the Upper North Fork Clearwater Subbasin where the model calculations were made. The St. Maries watershed is at a lower elevation (2,100 to 5,800 feet) than the Upper North Fork Clearwater Subbasin. Since solar radiation is stronger at higher elevations, the modeled energy inputs are conservative for these water bodies.

The heat flux amounts shown in Table 27 do not represent the entire heat budget of the streams, but only that from direct sunlight (insolation). This is the portion of heat flux the TMDL and, ultimately, vegetation management can address. Land management cannot significantly affect other environmental factors affecting temperature.

Table 27. Average daily solar radiation incident on a stream related to canopy closure as developed for the Upper North Fork Clearwater River.[1]

Canopy Density (percent)	Stream Orientation		
	North-South (watts/m²)	East – West (watts/m²)	SE-NW or SW-NE (watts/m²)
0	226	274	250
10	205	248	227
20	185	223	204
30	164	197	181
40	143	172	197
50	122	146	134
60	101	120	111
70	80	95	87
80	59	69	64
90	38	43	41
100	17	18	17.5

[1]SSTEMP model output (Dechert *et al*. 2001) based on the following calculations:
North-South = (100-target canopy percent)*2.1+1.7
East-West = (100-target canopy percent)*2.56+18
SE-NW or SW-NE = (100-target canopy percent)*2.33+17.5

Target Selection

The TMDL selects canopy cover by stream reach elevation as the target for load capacity goals for reducing heat load. Canopy cover can be allocated as a surrogate for heat load reduction that can be affected in part by vegetation management. It can also be related to thermal load reduction by the SSTEMP estimates provided in Table 27. Canopy cover can be mapped on a stream reach basis to facilitate management prescriptions in a TMDL implementation plan. It can easily be assessed using aerial photography techniques. Milestones in the implementation plan can be set on a 10-year basis to coincide with the normal frequency of aerial photographic surveys.

Applicable reference streams can be found in the St. Joe Subbasin above the Mosquito Creek confluence. This area was burned during the 1910 fires and has recovered seral timber stands. However, timber harvest has been less intensive than in watersheds of the St. Maries Subbasin. Bacon, Bean, and Yankee Bar Creeks are streams that could be used as reference. The streams of the upper St. Joe Subbasin currently support bull trout populations and most approach the 10 ^{o}C standard during August, when stream temperatures peak. These streams also approach full support of the salmonid spawning temperature standard.

Monitoring Points

Points of compliance were selected for temperature monitoring. These are provided below in Table 28. These sites can used to assess both rearing and spawning temperatures.

Table 28. Points of compliance for the St. Maries River temperature TMDLs.

Waterbody	Location	Beneficial Use Reconnaissance Program Monitoring Site
Gramp Creek	Near mouth	1996SCDAA047
Gold Center Creek	Near mouth	1996SCDAA045
Flewsie Creek	Near mouth	1996SCDAA048
Middle Fork of the St. Maries River	Near mouth	1996SCDAA040
West Fork St. Maries River	Near mouth	1998SCDAA021
Emerald Creek	Near mouth	1995SCDAB008
Santa Creek	Near mouth	1995SCDAB005
St. Maries River	At Cedar Creek	1997SCDAA033
St. Maries River	At Emerald Creek	To be Determined

Primary TMDL monitoring will be with aerial photography interpretation of canopy recovery over the streams. Aerial photography is currently repeated on a ten-year time frame. This time frame will allow a sufficient period to assess canopy recovery. In addition, a set number of representative sites should be assessed on the ground on a periodic basis using canopy densiometer methodology to ground truth and calibrate the aerial photograph interpretation. These monitoring issues should be further addressed and specified in the monitoring section of the implementation plan.

5.2.2 Load Capacity

Load capacity is stated in terms of canopy cover and the insolation rate required to maintain a maximum weekly maximum temperature (MWMT) of 10 ^{o}C (Table 28). A load capacity has been developed for each stream reach covering 200 feet of elevation. Equation 2 (page 72) is used to calculate the percent cover required for each stream reach. Under elevations of 4,000 feet the CWE model predicts greater than 100% canopy closure to maintain the 10 ^{o}C MWMT goal. Since this is not possible, canopy closure is defaulted to 100%. The St. Maries River watershed has an elevation range of 2,200 to 5,800 feet. A 100% canopy cover is required on all streams between 2,200 and 4,000 feet to achieve the10 ^{o}C MWMT goal. Even this goal may not be achievable on some stream reaches due to natural plant community type, stream width, or habitat type restrictions. Canopy cover goals are currently only met on a few of the 200 feet elevation increment reaches of the St. Maries River watershed.

Use of the CWE model and corroboration of its accuracy for predicting relationships between canopy cover, thermal input, and stream temperature has been developed in the *Upper North Fork Clearwater Temperature TMDLs* (Dechert *et al.* 2001). The application of the thermal model to the St. Maries River watershed is appropriate.

Critical Conditions

Critical conditions are a part of the load capacity analysis. For the St. Maries River Subbasin, critical conditions for temperature are low discharge conditions in August and early September (mid to late summer). The goal is set to meet 10 ^{o}C MWMT during this time period and the manageable thermal input is modeled to achieve the goal. Acute and chronic violations of the 10 ^{o}C MWMT goal may contribute to the lack of sufficiently high trout numbers of trout in the St. Maries River watershed (Table 11; Appendix B).

Table 29. Cumulative watershed effect calculated canopy cover required at stated elevations to maintain the 10 ^{o}C maximum weekly maximum temperature and corresponding heat load capacity from insolation.

Elevation Range	CWE Target Canopy Cover (%)	Heat Load Capacity[2] North-South oriented stream (watts/sq m)	Heat Load Capacity[2] East-West oriented stream (watts/sq m)	Heat Load Capacity[2] SWNE or SENW oriented stream (watts/sq m)
4,800 – 4,999	71	79	93	86
4,600 – 4,799	77	66	77	71
4,400 – 4,599	83	53	62	57
4,200 – 4,399	89	40	46	43
4,000 – 4,199	95	27	30	28
3,800 –3,999	101	17	18	17.5
3,600 – 3,799	108	17	18	17.5
3,400 – 3,599	114[1]	17	18	17.5
3,200 – 3,399	120[1]	17	18	17.5
3,000 – 3,199	126[1]	17	18	17.5
2,800 – 2,999	132[1]	17	18	17.5
2,600 – 2,799	139[1]	17	18	17.5
2,400 – 2,599	145[1]	17	18	17.5
2,200 – 2,399	152[1]	17	18	17.5

[1] Below 4,000 feet elevation the CWE model predicts a need for greater than 100% canopy closure to protect a maximum stream temperature of 10 ^{o}C MWMT. Since this is not possible, 100% canopy closure is set as the surrogate heat load capacity. In some cases, 100% canopy closure may not be achievable because of plant community type or habitat type restrictions.
[2] SSTEMP predicts insolation rates of 17-18 watts/m^2 for 100% canopy closure.

5.2.3 Estimates of Existing Pollutant Loads

The Santa-Fernwood, Clarkia, and Emida wastewater treatment facilties are point sources of thermal input to the St. Maries River Subbasin. Natural inputs include ambient air temperature, inflow ground water temperature, and direct insolation. Of these factors, only direct insolation can be estimated and managed through the vegetation management of stream canopy cover.

Table 30. General canopy cover estimate guide for aerial photo interpretation.[1]

Visibility on Aerial Photographs	Percent Canopy
Stream surface not visible	>90%
Stream surface slightly visible	76-90%
Stream surface visible in patches	61-75%
Stream surface visible, but banks are mostly not visible	46-60%
Stream surface visible and banks visible in places	31-45%
Stream surface and banks visible in most places	16-30%
Stream surface and banks visible	0-15%

[1] Table from IDL.

Canopy cover was surveyed using aerial photometry, assessed using the guidelines in Table 30, and ground verified by CWE crews. Insufficient canopy cover is the primary manageable temperature input. Current canopy coverage of the reaches of the St. Maries River Subbasin is provided in Tables 31a-e.

5.2.4 Temperature Load Allocation and Wasteload Allocation

The temperature allocation is comprised of the wasteload allocation of point sources and the load allocation of nonpoint sources.

Margin of Safety

Between 2,200 and 4,000 feet elevation the required canopy cover is 100%. Much of the St. Maries River watershed does not exceed 4,000 feet elevation. For stream reaches above 4,000 feet, the margin of safety is the existing shade above that required to satisfy thermal equations. Canopy cover of 100% is both the requirement and the limit of management for temperature below 4,000 feet. The 10 ^{o}C MWMT standard used is the federal standard.

Seasonal Variation

Heat loading capacity applicable to the St. Maries River watershed in relation to the EPA bull trout temperature standard is primarily a consideration during August and early September. Because of the seasonal progression in stream temperature, if a stream's annual temperature peak is targeted, and this peak is brought down to within criteria limits, then it can safely be assumed that the criteria will also be met at cooler times of the year. This is the basis of using the MWMT metric for criteria. The 10 °C MWMT criteria calculations for bull trout translates closely to the 9 °C daily average criteria for cutthroat.

Wasteload allocations were determined with respect to salmonid spawning periods. Therefore, stream flow and effluent discharge during May through September were used in calculating maximum acceptable effluent temperature.

Reasonable Assurance

Reasonable assurance is provided by nonpoint source implementation of BMPs based on land management agencies' assurance that reductions will occur. Additionally, trend monitoring will be used to document relative changes in various aquatic organism populations and in physical and chemical water quality parameters. This data will be used to assess overall progress towards attainment of water quality standards and related beneficial uses.

Background

The background temperature and thermal input to the temperature-listed waters of the St. Maries Subbasin are not known. Pre-canopy removal stream temperature and stream canopy cover were not measured. Significant reaches of the St. Maries River are too broad and shallow to effectively shade with vegetation. This stream configuration may have existed prior to development. It would not have and will not support vegetation communities capable of providing 100% canopy cover to the stream. Any TMDL implementation plan should note and account for these areas of natural thermal loading.

Reserve

No reserve is developed for this TMDL. The thermal capacity of the watershed has been exceeded by canopy removal. Canopy restoration, to the degree possible, is required to address the thermal loading.

Wasteload Allocation

There are three point sources of thermal input to the temperature-listed streams of the St. Maries Subbasin. These point sources are the Santa-Fernwood, Clarkia, and Emida wastewater treatment facilities. They were assigned wasteload allocations as follows.

Idaho water quality standards (IDAPA 58.01.02.401.03.a.v.) provide that in waters where stream temperature naturally exceeds criteria, point source must not increase stream temperature greater than 0.3 ^{o}C.

The following temperature limit equation was used to determine the impact of the wastewater treatment facilities on stream temperature:

$$T_E = \frac{[Q_E + (0.25*Q_S)] * [T_C + 0.3\,^{o}C] - [(0.25 * Q_S) * T_C]}{Q_E}$$

where T_E = effluent temperature
Q_E = effluent flow (cfs)
Q_S = stream flow (cfs)
T_C = applicable temperature criteria (^{o}C)
0.25 = 25% by volume mixing zone allowance

The 90th percentiles of effluent flows at each of the three locations were calculated using the facilities' Dishcarge Monitoring Reports. The Santa-Fernwood facility has an average high discharge of .278 cfs, while the Clarkia facility has an average high discharge of .130 cfs. Discharge values for the Emida facility were estimated from the Clarkia facility's discharge reports, as they are not required to monitor discharge. An average stream flow of 316 cfs, during the salmonid spawning period of May through September, was determined from Table 3 (page 27). The applicable temperature criteria of 9 ^{o}C was used. These values revealed that effluent temperatures of 95 ^{o}C and 188 ^{o}C for the Santa-Fernwood and Clarkia/Emida facilities, respectively, would be needed to cause an in-stream temperature increase of greater than 0.3 ^{o}C.

The St. Maries-area wastewater treatment facilities are not required to monitor and record effluent temperature, however, it was possible to examine maximum effluent temperatures at a nearby facility, Kootenai-Ponderay Sewer District. This system employs the same wastewater stabilization pond technology used by the St. Maries-area facilities. The maximum monthly effluent temperature for the time period examined (February 2002 through May 2003) was 30.32 ^{o}C. As such, the St. Maries-area wastewater treatment facilities are assigned wasteload allocations of 35 ^{o}C daily maximum effluent temperature. The facilities can be reasonably expected to meet this standard because, like the Kootenai-Ponderay facility, they are not likely to produce effluent at temperatures greater than 35 ^{o}C. Additionally, a 35 ^{o}C daily maximum allocation provides a built-in margin of safety as it is conservative when compared to the temperatures described above as necessary to increase stream temperature by 0.3 ^{o}C.

Load Allocation

Load allocations have been developed, establishing target load levels at which streams are expected to meet temperature criteria. The load allocations must result in 100 percent canopy cover in streams below 4,000 feet in elevation, with exceptions noted below. Load allocations for each steam segment in the subbasin are presented in Table 31.

Canopy Habitat Type Limitations

Some habitat types found along streams are not capable of sustaining sufficient stream canopy coverage. These habitat types either have physical limitations that preclude sufficient tree density to develop complete canopy coverage that do not support tree establishment to any significant degree. In addition, a stream may be too broad to be effectively shaded by trees. The St. Maries River below the Emerald Creek confluence has a broad and shallow channel that is sufficiently wide to preclude effective shading by vegetation during the mid-day hours. The channel morphology does not appear to be the result of sediment deposition. Accelerated sediment deposition would cause braiding in a generally low gradient stream like the St. Maries River. But no braiding is evident. The broad, shallow morphology between Emerald and Santa Creeks appears to be a natural feature. Although it is generally deep, the river is sufficiently broad to preclude effective shading below the Santa Creek confluence. Stream segments with canopy habitat type limitations are identified with a footnote in Table 31.

These segments were assigned interim target canopy cover levels. The actual maximum potential canopy for these streams will be determined by a committee of forest and riparian professionals during the implementation phase of TMDL development. After a determination is made, the temperature TMDL will be amended to reflect the new values.

Table 31. Watershed temperature TMDLs – Cumulative Watershed Effects (CWE) calculated percent canopy cover and heat loading.

[1]Interim target canopy cover; physical habitat limitations in these segments make it unlikely that current target levels will be reached. Final target canopy cover to be determined during the implementation phase.

Remaining Available Load

The remaining load is allocated to segments of the watershed based on canopy requirements. The elevation range of the stream segments is used to develop the target canopy cover using the CWE temperature relationship (Tables 31a-e). These targets are in many cases greater than 100% because the St. Maries watershed exceeds 4,000 feet elevation in only its upper stream reaches. These target values were revised to 100% canopy cover. Segments over 4,000 feet require less than 100% canopy cover. The required canopy is subtracted from 100% and the existing amount of canopy cover restoration required is calculated. Using the SSTEMP model outputs for canopy cover and stream orientation, the target heat load capacity was calculated for each segment. Based on current canopy cover and the SSTEMP model outputs for percentage canopy cover, current heat loading is estimated. Subtraction and division provide the target heat load reduction required for each segment. The level of canopy cover currently present is provided in Figures 8a-c. The target canopy cover for all segments is provided in Figures 9a-c.

Monitoring Provisions

Temperature will be monitored with continuous recorders in streams after the canopy has reached 70% of its potential in a given stream. Temperature recorders will be placed in representative locations on third order reaches of the streams as near as feasible to the points of compliance. Temperature data developed will be compared with the current temperature standards to assess temperature standard exceedences. Biomonitoring of macroinvertebrates and fish will be completed to assess the status of the cold water aquatic life.

Feedback Provisions

When temperatures meet the standard or natural background level, further canopy-increasing activities will not be required in the watershed. Best management practices will be prescribed by the revised TMDL with provisions to maintain and protect canopy cover of the streams. Regular monitoring of the beneficial use will be continued for an appropriate period to document maintenance of the full support of the use (cold water).

5.2.5 Conclusions

The St. Maries River Subbasin is not in the St. Joe bull trout recovery area where the federal temperature standard of 10 ^{o}C MWMT applies. However, continuous temperature monitoring in tributaries of the St. Maries River demonstrates that the salmonid spawning standard is violated for significant periods of the critical season. A temperature TMDL based on the CWE relationship between canopy cover, elevation, and direct insolation input to the streams was developed. The watershed topography is between 2,200 and 5,800 feet elevation. The shade requirement between 2,400 and 4,000 feet is 100% or full potential shade. Lesser amounts of shade are progressively necessary above 4,000 feet. Figures 8a-e provide the current level of canopy cover provided the streams, while Figures 9a-e depict the canopy cover required. The St. Maries River below the Emerald Creek confluence is sufficiently broad that only 30% shading is possible, except in a 19 mile stretch, where 40% shading is possible (Figure 9-e).

5.3 Implementation Strategies

DEQ and designated lead agencies responsible for TMDL implementation will make every effort to address past, present, and future pollution problems in an attempt to link them to watershed characteristics and management practices designed to improve water quality and restore the beneficial uses of the water body. Any and all solutions to help restore beneficial uses of a stream will be considered as part of a TMDL implementation plan in an effort to make the process as effective and cost efficient as possible. Using additional information collected during the implementation phase of the TMDL, DEQ and the designated agencies will continue to evaluate suspect sources of impairment and develop management actions appropriate to deal with these issues.

DEQ recognizes that implementation strategies for TMDLs may need to be modified if monitoring shows that the TMDL goals are not being met or significant progress is not being made toward achieving the goals.

Time Frame

For sediment TMDLs, 30 years have been allotted for meeting load allocations. This time frame will permit two or three large channel forming events to occur in the stream.

Primary TMDL monitoring of temperature TMDLs will be with aerial photograph interpretation of canopy recovery over the streams. Aerial photography is repeated by the USFS on a 10-year time frame. This time frame will allow a sufficient period to assess canopy recovery. In addition, a set number of representative sites should be assessed on a periodic basis using canopy densiometer methodology to ground truth and calibrate the aerial photograph interpretation.

Approach

TMDLs will be implemented through continuation of ongoing pollution control activities in the subbasin. The designated agencies, WAG, and other appropriate public process participants are expected to:

-- Develop BMPs to achieve load allocations
-- Give reasonable assurance that management measures will meet load allocations through both quantitative and qualitative analysis of management measures
-- Adhere to measurable milestones for progress
-- Develop a timeline for implementation, with reference to costs and funding
-- Develop a monitoring plan to determine if BMPs are being implemented, if individual BMPs are effective, if load allocations and waste load allocations are being met, and whether or not water quality standards are being met

The designated agencies will recommend specific control actions and will then submit the implementation plan to DEQ. DEQ will act as a repository for approved implementation plans.

Responsible Parties

Development of the final implementation plan for the St. Joe River TMDL will proceed under the existing practice established for the state of Idaho. The plan will be cooperatively developed by DEQ, the St. Joe WAG, the affected private landowners, and other “designated agencies” with input from the established public process. Of the three entities, the WAG will act as the integral part of the implementation planning process to identify appropriate implementation measures. In addition to the designated agencies, the public, through the WAG and other equivalent processes, will be provided with opportunities to be involved in developing the implementation plan to the maximum extent practical.

Monitoring Strategy

In-stream monitoring of the beneficial uses (cold water and salmonid spawning) support status during and after implementation of sediment abatement projects will establish the final sediment load reduction required by the TMDL. In-stream monitoring, which will determine if the threshold values have been met, will be completed every year on randomly selected sites on each stream order in the subbasin after 70% of the plan has been implemented. Monitoring will be conducted using the DEQ-approved monitoring procedure at the time of sampling. Identical measurements will be made in appropriate reference streams where beneficial uses are supported.

Temperature will be monitored on the streams with continuous recorders after the canopy has reached 70% of its potential. Temperature recorders will be placed in representative locations on third order reaches of the streams as near as feasible to the points of compliance. Temperature data developed will be compared with the current temperature standards to assess temperature standard exceedences. Biomonitoring of macroinvertebrates and fish will be completed to assess the status of the cold water aquatic life.

5.4 Conclusion

Two TMDLs were developed for streams in the St. Maries River Subbasin. The TMDLs addressed sediment and temperature only, as no other pollutants were found to be limiting the support of beneficial uses in the subbasin.

DEQ recommends that Gramp Creek be delisted for bacteria and that Santa Creek be delisted for dissolved oxygen limitation.

None of the streams in the subbasin were found to be impaired by excess nutrients. As such, it is recommended that the St. Maries River and Thorn, Alder, and Santa Creeks be delisted for excess nutrients.

Sediment modeling and WBAGII score analysis revealed that the St. Maries River, including the West and Middle Forks, and Alder, John, Charlie, Santa, Tyson, Carpenter, Emerald, Renfro, Thorn, and Crystal Creeks are impaired by sediment. A single sediment TMDL was written for the entire subbasin. Gold Center, Flewsie, and Gramp Creeks were not found to be impaired by sediment. It is recommended that they be delisted for this pollutant.

A temperature TMDL was developed for the St. Maries River, including the West and Middle Forks, and Santa, Emerald, Gold Center, Flewsie, and Gramp Creeks.

Conditions in all of the water bodies listed above will be monitored on an ongoing basis. This will ensure that beneficial uses currently supported remain that way and that water bodies not in full support of their beneficial uses are making progress through the implementation process.
